PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY

OTITIS MEDIA (ACUTE): AURALGAN is indicated for relief of pain and reduction of inflammation in the congestive and serous stages of acute otitis media. It is effective adjuvant therapy when antibiotics or sulfonamides are administered systemically.

Administration: Otitis media (acute): Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching ear with dropper. Then, moisten cotton pledget with AURALGAN and insert into the meatus. Repeat every one to two hours (or three or four times a day).

REMOVAL OF CERUMEN: AURALGAN facilitates the removal of excessive or impacted cerumen.

Administration for Removal of Cerumen: Instill AURALGAN three times daily for two days to help detach cerumen from wall of canal and facilitate removal of plug. Irrigate with warm water.

Note: Keep well closed. Do not rinse dropper after use.

SUPPLIED: No. 1000 – AURALGAN Otic Solution, in package containing 15 ml (1/2 fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY.
ON PRESCRIPTION ONLY.

Expressly for kids with colds that cough*

orange-pineapple flavored

Tuss-Ornade® cough/cold liquid

Each 5 ml. teaspoonful contains 5 mg. caramiphen edisylate; 2 mg. chlorpheniramine maleate; 15 mg. phenylpropanolamine hydrochloride; isopropamide iodide equivalent to 0.75 mg. of isopropamide; and alcohol, 7.5%.

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

* **Indications**

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Lacking in substantial evidence of effectiveness as a fixed combination: For relief from coughing, upper respiratory congestion and hypersecretion associated with the common cold, sinusitis, vasomotor rhinitis and allergic rhinitis.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Hypersensitivity to any component; concurrent MAO inhibitor therapy; severe hypertension; bronchial asthma; coronary artery disease; stenosing peptic ulcer; pyloroduodenal or bladder neck obstruction. Do not use 'Tuss-Ornade' Liquid in children less than six months of age or under 15 lbs. in weight. Do not use 'Tuss-Ornade' *Spansule* capsules in children under 12 years of age.

Warnings: Warn vehicle or machine operators of possible drowsiness. Warn patients of possible additive effects of alcohol and other C.N.S. depressants.

Usage in Pregnancy: Use in pregnancy, nursing mothers and women who might bear children only when potential benefits have been weighed against possible hazards. An inhibitory effect on lactation may occur.

Effect on PBI Determination and I^{131} Uptake: The iodine in isopropamide iodide may alter PBI test results and will suppress I^{131} uptake; use thyroid tests unaffected by exogenous iodides.

Precautions: Use with caution in persons with cardiovascular disease, glaucoma, prostatic hypertrophy, hyperthyroidism.

Adverse Reactions: Drowsiness; excessive dryness of nose, throat or mouth; nervousness, insomnia; nausea, vomiting, diarrhea; rash; dizziness; weakness; tightness of chest; angina pain; abdominal pain; irritability; palpitation; headache; incoordination; tremor; difficulty in urination; thrombocytopenia, leukopenia; convulsions; hypertension, hypotension; anorexia; constipation; visual disturbances; iodine toxicity (acne, parotitis); dysuria; epigastric distress.

Supplied: 'Tuss-Ornade' Liquid: An orange-pineapple flavored liquid in 16 fl. oz. bottles. For patients 12 years or older, 'Tuss-Ornade' *Spansule* capsules (each capsule contains 20 mg. caramiphen edisylate; 8 mg. chlorpheniramine maleate; 50 mg. phenylpropanolamine HCl; and isopropamide iodide equivalent to 2.5 mg. of isopropamide), in bottles of 50 and 500 capsules.

Advertising and Subscription Information

Advertising Offices: 535 N Dearborn St, Chicago, IL 60610, Area Code 312, 751-6675; and 600 Third Ave, New York, NY 10016, Area Code 212, 867-6640.

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

Subscription Rates: The yearly rates for the AMERICAN JOURNAL OF DISEASES OF CHILDREN is as follows: for members of the AMA, $1.50, included in the annual membership dues; for non-members, $24 for one year, $40 for two years in the United States and US possessions; all other countries, $34 for one year, $60 for two years. Special yearly price to residents, interns, and medical students in the United States and US possessions, one year, $12; two years, $20. Address all subscription communications to Circulation-Fulfillment Department. Phone: 312, 751-6079.

Change of Address: POSTMASTER, send address changes to Helen R. Mazur, Director, Circulation-Fulfillment. Notification of address changes should be sent at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AMERICAN JOURNAL OF DISEASES OF CHILDREN (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

ACTIFED-C® Expectorant ℂ

Each 5 cc teaspoonful contains: codeine phosphate 10 mg (Warning—may be habit-forming); Actidil® brand triprolidine HCl 2 mg; Sudafed® brand pseudoephedrine HCl 30 mg; guaifenesin 100 mg. Preservatives are methylparaben 0.1% and sodium benzoate 0.1%.

With the cough-stopping power of codeine.

Controls Excessive Coughing Without Preventing Productive Expectoration

Persistent, repetitive, dry coughs can be a problem in the pediatric patient, particularly at night when it often disturbs sleep. Actifed-C is made for this type of cough.

It contains codeine to reduce severity and persistence plus guaifenesin to liquefy and ease the expulsion of mucus. Moreover, Actifed-C is the only cough medication that contains triprolidine and pseudoephedrine... the decongestant/antihistamine combination that has been part of the NASA Space Medicine Kit since 1968.

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Lacking substantial evidence of effectiveness as a fixed combination": For the symptomatic relief of cough in conditions such as: the common cold, acute bronchitis, allergic asthma, bronchiolitis, croup, emphysema, tracheobronchitis.

Final classification of the less-than-effective indications requires further investigation.

Warning: Use in Pregnancy: Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus.

Precautions: Although pseudoephedrine hydrochloride causes virtually no pressor effect in normotensive patients, it should be used with caution in patients with hypertension. In addition, even though triprolidine hydrochloride produces only a low incidence of drowsiness, appropriate precautions should be observed.

Side Effects: The great majority of patients will not have any side effects. Only certain patients, sensitive to one or another of the ingredients, may note mild stimulation or mild sedation.

Supplied: Bottles of 1 pint. Complete literature available on request from Professional Services Dept. PML.

Not recommended for use in children under 2 years of age.

ONE HUNDRED YEARS WELLCOME

Get them on their feet again!

When winter colds are at their worst, Naldecon® is at its best!

(antihistamine/decongestant)

Winter colds can get even the best of sports down. But Naldecon® (antihistamine/decongestant) can get them up and going again with fast symptomatic relief!

With balanced formulation for maximum relief and minimum side effects.

Naldecon combines antihistamines from two chemical classes, as well as two decongestants, to offer prompt symptomatic relief and minimize side effects. That's why it's the ideal choice for busy, active patients who aren't going to let a cold stop them.

An ethanolamine for long-lasting antihistamine activity

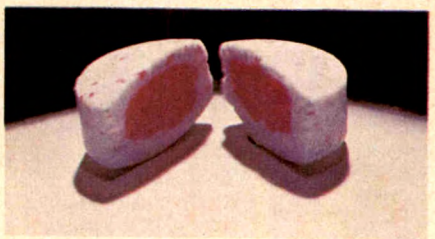
An alkylamine for minimal antihistamine drowsiness

Phenylpropanolamine for prolonged decongestant effectiveness

Phenylephrine for additional decongestant action with little or no C.N.S. stimulation.

With a unique tablet designed for easy titrating and hours of sustained relief.

With Naldecon tablets, adjusting dosage without losing the convenience of sustained relief is a snap! The unique Naldecon tablet is scored so that just a little thumb pressure on each half of the tablet breaks it neatly in two. Half tablet or whole, the outer layer rapidly dissolves for prompt effectiveness and the slow-release inner core provides additional hours of relief.



With enough dosage forms to keep the entire family skiing.

Naldecon's full line of forms for all ages includes "kid-tested and flavor-approved" pediatric liquids.

- Adult tablets and syrup.
- Pediatric syrup for infants and children, 6 months to 12 years old.
- Pediatric drops for infants and children, 3 months to 6 years old.

Naldecon® salutes the world's best.

XIII OLYMPIC WINTER GAMES LAKE PLACID 1980

The world's best winter athletes gather in Lake Placid this year for the quadrennial spectacle of the Olympic Winter Games. Bristol Laboratories takes great pride in having Naldecon designated Official Supplier to these XIII Olympic Winter Games.

We salute the splendid amateur athletes whose memorable feats are once again an inspiration to all of us who have trouble staying on our feet in the winter.

Naldecon®
(antihistamine/decongestant)

Official Supplier to the XIII Olympic Winter Games in Lake Placid, New York.

XIII OLYMPIC WINTER GAMES LAKE PLACID 1980

Only Naldecon® offers the winter cold sufferer the effectiveness of *two* antihistamines and *two* decongestants, proportioned to minimize their undesirable side effects.

Naldecon® has:

- **Staying power.** Sustained release: an outer layer for immediate relief, an inner core for hours more.
- **Flexibility.** Dosage forms for all ages and a unique scored tablet for fractionalized dosage, without losing the sustained release.
- **Balance.** Formulated to provide maximum effectiveness with minimum side effects.

NALDECON® Tablets, Syrup, Pediatric Drops, and Pediatric Syrup For Oral Use Only

5600DIMO-11 1/78

DESCRIPTION:

Each sustained-action tablet contains:	For immediate action	For delayed action	Total content
Phenylpropanolamine hydrochloride	20.0 mg.	20.0 mg.	40.0 mg.
Phenylephrine hydrochloride	5.0 mg.	5.0 mg.	10.0 mg.
Phenyltoloxamine citrate	7.5 mg.	7.5 mg.	15.0 mg.
Chlorpheniramine maleate	2.5 mg.	2.5 mg.	5.0 mg.

Each teaspoonful (5 ml.) of syrup contains:

Phenylpropanolamine hydrochloride	20.0 mg.
Phenylephrine hydrochloride	5.0 mg.
Phenyltoloxamine citrate	7.5 mg.
Chlorpheniramine maleate	2.5 mg.

Each pediatric formulation contains the following ingredients:	Pediatric Syrup each 5 ml. contains:	Pediatric Drops each 1-ml. dropper contains:
Phenylpropanolamine hydrochloride	5.0 mg.	5.0 mg.
Phenylephrine hydrochloride	1.25 mg.	1.25 mg.
Phenyltoloxamine citrate	2.0 mg.	2.0 mg.
Chlorpheniramine maleate	0.5 mg.	0.5 mg.

ACTIONS: Naldecon is useful for the relief of nasal congestion associated with pollen allergy and minor infections of the upper respiratory tract (the common cold, nasopharyngitis, acute and chronic sinusitis). Naldecon tablets are compounded with half of each ingredient in the outer layer for immediate action and the remainder in the slowly disintegrating core for a sustained effect.

The actions and uses of individual ingredients in the formulation are as follows:

Phenylpropanolamine Hydrochloride

Phenylpropanolamine hydrochloride[1] acts similarly to ephedrine. It is effective orally for the symptomatic control of allergic manifestations, such as perennial hay fever and bronchial asthma. Its action is more prolonged than that of ephedrine, and it is not so apt to produce anxiety complex as is ephedrine.

Phenylephrine Hydrochloride

Phenylephrine hydrochloride[2] is a more powerful vasoconstrictor than synephrine tartrate. When administered orally, it is a vasopressor and relatively nontoxic. The pressor and anti-allergic effects of the drug are produced by oral administration. Therefore, this route may be employed in the treatment of orthostatic hypotension and allergic disorders. The comparatively larger doses required for effective oral treatment are only rarely accompanied by mild gastrointestinal symptoms. These may be avoided by administering the drug after meals.

Phenyltoloxamine Citrate

Phenyltoloxamine citrate[3] is a β-dimethylaminoethyl ether of orthobenzylphenol; as such it belongs to the group of antihistaminics exhibiting the aminoalkyl ether structure. The incidence of side effects is low; at recommended doses, soporific effects occur in less than 7% of patients.

Chlorpheniramine Maleate

Chlorpheniramine maleate[4] has good therapeutic efficacy and low incidence of side effects. It is comparable in therapeutic efficacy to other antihistaminics although administered in very low dosage.

INDICATIONS: Relief of distressing symptoms of colds and other upper respiratory infections, acute and chronic sinusitis, hay fever, and other pollen allergies:

Rhinorrhea	Lacrimation
Postnasal drip	Sneezing
Nasal congestion	Itching of eyes and nose
Sinus congestion	Head stuffiness

CONTRAINDICATIONS: Sensitivity to any of the ingredients.

PRECAUTIONS: This preparation may cause drowsiness. The patient should be cautioned against engaging in operations requiring alertness such as driving an automobile, operating machinery, etc. Do not exceed the recommended dose unless directed by a physician. Individuals with high blood pressure, heart disease, diabetes mellitus, thyroid disease, glaucoma, peripheral vascular disease or prostatic hypertrophy should use only as directed by a physician.

DOSAGE: This chart represents single dosages for the products listed below. Usual dosage schedule for Naldecon Pediatric Drops, Naldecon Pediatric Syrup and Naldecon Syrup is every 3 to 4 hours, not to exceed four doses in a 24-hour period. For sustained-action Naldecon Tablets, doses should be administered on arising, in midafternoon, and at bedtime.

Single Dosage for...	Pediatric Drops	Pediatric Syrup	Syrup	Tablets
3 to 6 months	1/4 ml.			
6 to 12 months	1/2 ml.	1/2 teaspoonful		
1 to 6 years	1 ml.	1 teaspoonful		
6 to 12 years		2 teaspoonfuls	1/2 teaspoonful	1/2 tablet
over 12 years			1 teaspoonful	1 tablet

Instructions for Authors

General Information.—Send manuscripts by first-class (not registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation

All the elements of a manuscript should be submitted in **triplicate, double-spaced throughout.** Use heavy-duty white bond paper, 22 × 28-cm, and 4-cm margins. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda

Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor

Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References

These must be listed in order of their appearance in the text, and typed double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 131:295-296, 1977.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons Inc, 1965, pp 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders Co, 1974, pp 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations

Submit in triplicate, unmounted, and untrimmed. Send only high contrast glossy prints (not photocopies or original artwork); preferred size 12.5 × 18-cm. Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

NTID

If You Suspect a Hearing Loss, Doctor...Please... Don't Wait

Even infants as young as six months who suffer a hearing loss can be helped...if they receive early treatment.

But the key is detection.

Please don't wait for time to confirm your suspicions. Refer your patient immediately to an otolaryngologist, otologist or audiologist. As the child matures, an ophthalmological exam may also be indicated.

The National Technical Institute for the Deaf, a part of Rochester Institute of Technology, prepares nearly 1,000 deaf college students annually for successful technical careers. Over the past decade some important facts have been discovered about the detection and treatment of hearing disorders. We'd be pleased to share them with you, just for the asking.

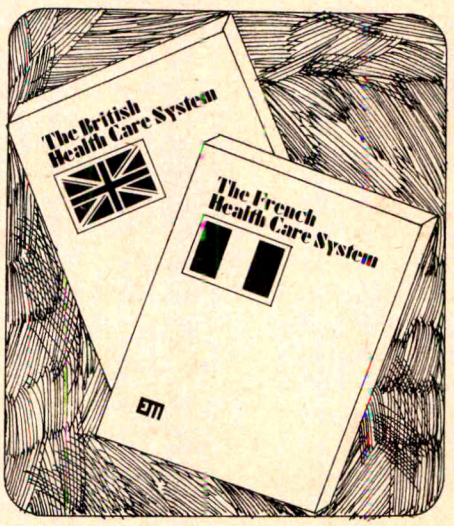
in depth studies of the health care systems of Britain and France...



how they operate and what they mean to users and to people who work in them.

These highly readable, comprehensive studies, prepared by a London research firm and published by the American Medical Association, offer an opportunity to examine other system's organization, problems, and achievements.

You'll learn how and why the present systems evolved...how they are financed...the range and quality of services available...the training and distribution of medical personnel ...and what effects each system has had upon the health of the general population.

Everyone in the medical profession should read both of these fascinating studies on how other nations have organized the delivery of health care.

Both books will be available Fall of 1976. To order your copies, write ORDER DEPT., AMA P.O. Box 821, Monroe, WI 53566. **The French Health Care System** (OP-460) costs $3.50; the **British Health Care System** (OP-461), $7.50. The set is $10. Remittance must accompany order. Allow 4-5 weeks for delivery.

Brief Summary

E.E.S.®

(ERYTHROMYCIN ETHYLSUCCINATE)

Indications: *Streptococcus pyogenes* (Group A beta hemolytic streptococcus)—Upper and lower respiratory tract infections, skin, and soft tissue infections of mild to moderate severity where oral medication is preferred. Therapy should be continued for 10 days.

Alpha-hemolytic streptococci (viridans group)—Short-term prophylaxis of bacterial endocarditis prior to dental or other operative procedures in patients with a history of rheumatic fever or congenital heart disease who are hypersensitive to penicillin.

S. aureus—Acute infections of skin and soft tissue of mild to moderate severity. Resistant organisms may emerge during treatment.

S. pneumoniae (D. pneumoniae)—Upper and lower respiratory tract infections of mild to moderate degree.

M. pneumoniae—For respiratory infections due to this organism.

Hemophilus influenzae: For upper respiratory tract infections of mild to moderate severity when used concomitantly with adequate doses of sulfonamides. Not all strains of this organism are susceptible at the erythromycin concentrations ordinarily achieved (see appropriate sulfonamide labeling for prescribing information).

Treponema pallidum—As an alternate treatment in patients allergic to penicillin.

C. diphtheriae and C. minutissimum—As an adjunct to antitoxin. In the treatment of erythrasma.

Entamoeba histolytica—In the treatment of intestinal amebiasis.

L. monocytogenes—Infections due to this organism.

Legionnaires' Disease—Although no controlled clinical efficacy studies have been conducted, *in vitro* and limited preliminary clinical data suggest that erythromycin may be effective in treating Legionnaires' Disease.

Establish susceptibility of pathogens to erythromycin, particularly when *S. aureus* is isolated.

Contraindications: Known hypersensitivity to erythromycin.

Warnings: Safety for use in pregnancy has not been established.

Precautions: Exercise caution in administering to patients with impaired hepatic function. There have been reports of hepatic dysfunction, with or without jaundice, occurring in patients receiving oral erythromycin products. Recent data from studies of erythromycin reveal that its use in patients who are receiving high doses of theophylline may be associated with an increase of serum theophylline levels and potential theophylline toxicity. In cases of theophylline toxicity and/or elevated serum theophylline levels the dose of theophylline should be reduced while the patient is receiving concomitant erythromycin therapy. Surgical procedures should be performed when indicated.

Adverse Reactions: Dose-related abdominal cramping and discomfort. Nausea, vomiting, and diarrhea infrequently occur. During prolonged or repeated therapy, there is a possibility of overgrowth of nonsusceptible bacteria or fungi. Mild allergic reactions such as urticaria and other skin rashes may occur. Serious allergic reactions, including anaphylaxis, have been reported.

Infant Formula for 12 Months? Think of it as Nutritional Insurance

That's why you should specify that new mothers keep their babies on breast milk or infant formula for a full 12 months.

Switching to cow's milk in the first year is not advisable. The high sodium content and the high protein content of cow's milk may increase the risk of dehydration and hypernatremia when diarrhea or other conditions increase the demand for water. Cow's milk feedings may place infants at risk for developing iron deficiency. And cow's milk is a poor source of copper and Vitamin C.[1]

Enfamil Provides Balanced Nutrition

ENFAMIL infant formula is patterned after breast milk and is a good source of digestible heat-treated protein, polyunsaturated fat, vitamins and minerals.

Recommend ENFAMIL until the end of the first year for infants who aren't breast feeding or who stop breast feeding.

For a more in-depth discussion of this subject, as well as other aspects of infant nutrition, an educational newsletter series entitled "Dialogues in Infant Nutrition" is available. This is part of a continuing education program on infant nutrition. For copies of the newsletter, contact your Mead Johnson Representative or Health Learning Systems, 1455 Broad Street, Bloomfield, New Jersey 07003.

Progress and the Little Gray Pill

The superiority of synthetic levothyroxine sodium over thyroid extracts in the treatment of hypothyroidism seems established. The exciting developments in our understanding of thyroid physiology during recent years must parallel the excitement that accompanied the first demonstration of the effective control of hypothyroidism by the use of extracts from animal thyroid glands. Those of us who have witnessed some of these advances remember the excitement that they produced, and we have enjoyed and appreciated the advantages that they have provided. Progress is always rewarding, and I agree with Penny and Frasier (p 16) that synthetic levothyroxine is the drug of choice in the treatment of hypothyroidism in the year 1979. However, I am compelled to add a word in defense of an old and reliable friend, namely, the little gray pill of USP desiccated thyroid. To do less would seem unjust.

For many years, I have prescribed levothyroxine for my new patients with hypothyroidism, and I agree that it offers several advantages, most all of which represent convenience rather than demonstrated clinical importance. The many thousands of patients successfully treated with USP thyroid preparations attest to their value.

In treating patients who have hypothyroidism, every physician knows or should know that the response to thyroid hormone varies no matter in what form the drug is administered, and reports of triiodothyronine-induced hyperthyroidism in an occasional patient treated with USP thyroid preparations should be no surprise. More surprising, of greater interest, and perhaps of greater importance, is the fact that the patients described by Penny and Frasier did not have clinical evidence of hyperthyroidism, even after receiving USP thyroid for years, during which time they (at least intermittently) had elevated levels of circulating triiodothyronine in the presence of normal levels of thyroxine.

If the chemical findings in the patients described accurately reflect chemical changes in all patients treated with USP thyroid, a generation of persons has grown up with hypertriiodothyronemia. If these many thousands of persons have suffered ill effects from such a chemical abnormality, they have not come to our attention; indeed, the evidence is to the contrary.

At the present time, approximately 40% of all patients in the United States receiving thyroid hormone therapy are taking USP thyroid. Many of them justifiably resist changing to a new preparation after enjoying years of satisfactory, even dramatic, response to the little gray pill. Further, many physicians with years of experience using USP thyroid have learned how to use these preparations and appreciate their effectiveness and reliability. They, too, will likely be more impressed by clinical success than the demonstration of a poorly understood chemical change in the blood.

Levothyroxine is rapidly replacing USP thyroid, and so it should; but USP thyroid, like levothyroxine, must be properly administered. When so administered, either preparation can be expected to control hypothyroidism satisfactorily. As we watch the passing of USP thyroid therapy, let us not be too critical of the little gray pill, for its record of success is long and enviable.

Functioning Tumors

It was 1952 when Hawfield and Daisley[1] described in detail the clinical picture and the diagnostic evaluation of the condition of a 13-month-old girl with severe chronic diarrhea, whose abnormal stools ceased promptly after removal of a ganglioneuroma from the right adrenal gland. They wrote, "Laboratory efforts to identify an endocrine function of the tumor removed in this case failed to reveal any functional secretion. Despite this fact, the clinical improvement indicates beyond a doubt that the tumor did have an endocrine function and was responsible for the presenting signs and symptoms."

Seven years later, Dicke and coworkers[2] and Greenberg and Gardner[3] simultaneously reported evidence of increased catecholamine production in patients with ganglioneuroma and chronic diarrhea. Since the urinary excretion of the various compounds returned to normal after excision of the tumor, the catecholamines were believed to be important in the cause of the diarrhea, although the exact mechanism was not clear. Subsequent studies by numerous investigators confirmed that most neuroblastomas and ganglioneuroblastomas were hormone-producing tumors and could synthesize dopamine and norepinephrine. Measurement of these compounds and their metabolites became an important tumor marker, and an aid in diagnosis and follow-up care of patients. Although most children with these neoplasms excreted increased amounts of catecholamines, very few of them had chronic diarrhea. Furthermore, patients with pheochromocytomas who had a sharp elevation of norepinephrine and epinephrine output seldom had diarrhea. It seemed probable that humoral substance(s) other than catecholamines were responsible for the severe disturbance of gastrointestinal (GI) function in certain patients with neurogenic tumors.[4]

The mystery remained until 1973 when Bloom et al[5] found vasoactive intestinal peptide (VIP) in a retroperitoneal ganglioneuroblastoma of an adult with the watery diarrhea, hypokalemia, achlorhydria syndrome. Then Swift et al[6] reported VIP in a thoracic ganglioneuroma from a 5-year-old girl who had diarrhea, stridor, and abnormally high quantities of catecholamines and metabolites in her urine. The diarrhea ceased after partial removal of the tumor and a decrease in VIP levels, even though catecholamine output remained elevated. This evidence implicated the GI hormone VIP as the culprit in causing the diarrhea, and demonstrated that both VIP and catecholamines can be produced by neurogenic tumors. Other investigators subsequently described similar findings.

The vasoactive effects of VIP and norepinephrine are antagonistic; VIP is a potent vasodilator and norepinephrine is a potent vasoconstrictor. Thus, children with the ganglioneuroma-diarrhea syndrome potentially are at risk, particularly during surgical excision of their tumors. Hypotensive or hypertensive crises can develop depending on the predominant hormone released by the tumor. Although such events are uncommon in children, preoperative and intraoperative management, as described by Kaplan and his colleagues (p 21), provides optimum care to the patient whose ganglioneuroma secretes both VIP and norepinephrine.

It is not surprising that both peptide hormone and catecholamine production have been identified in sympathetic nervous system tumors. Ganglion cells belong to the amine precursor uptake and decarboxylation (APUD) series that produce more than 35 physiologically active peptides and a small number of active amines.[7] These cells are widely distributed throughout the body and constitute the diffuse neuroendocrine system, whose central division contains the neuroendocrine and endocrine cells of the hypothalamic-pituitary axis and pineal gland and whose peripheral division includes all the APUD cells outside this region. The majority of the peripheral cells are located in the GI tract and the pancreas, but APUD cells also are found in the thyroid, parathyroid, adrenal medulla, sympathetic nervous system, and other areas. These cells at one time were presumed to have a common origin from neural crest ectoderm. Now they are thought to be "neuroendocrine programmed," arising either in the embryonic epiblast or in one of its descendants.

Studies have shown that there is

structural similarity among many of the biologically active peptides, ie, glucagon and secretin have 14 amino acid identities. Some gut hormones, such as cholecystokinin, are common to both intestinal tract and brain, and may effect hypothalamic activity and be involved in control of appetite.[8] Contrariwise, central neuronal peptides have been found in endocrine cells of the intestine and pancreas, ie, somatostatin may play a role in relation to the GI portal system as well as in inhibiting growth hormone release.

It is clear that our perspective of endocrine cells and hormones has been broadened considerably by the recent explosive increase in new knowledge. Cells capable of producing peptides and amines are located throughout the body. Words such as "GI hormones" or "brain hormones" are too restrictive. Neoplasms arising from a variety of tissues can harbor populations of cells that are capable of secretory product production. Many of them are named according to their secretory product, ie, insulinoma, glucagonoma, somatostatinoma, VIPoma. Although the majority of these tumors have been described in adults to date, it is important that child-care physicians become familiar with the signs and symptoms caused by hypersecretion of the major peptide and amine hormones. Unexplained disorders involving diarrhea, hypoglycemia or hyperglycemia, flushing, hypertension, etc, may be caused by excessive production of these secretory products by tumors.

Of equal importance is an understanding of the multiple endocrine adenomatosis syndromes.[9] These are familial disorders characterized by the presence of hyperplasia or tumor that involves one or more endocrine gland concurrently. Pluriglandular disease may be masked for many years by a clinical picture that suggests single endocrine gland involvement, or signs and symptoms of multiple organ involvement can develop simultaneously. When one affected family member has been identified, others should be evaluated for an endocrinopathy.

Multiple endocrine adenomastosis I (Wermer's syndrome or multiple endocrine neoplasia type 1) is characterized by the concomitant occurrence of benign tumors of the anterior pituitary gland, hyperplasia of the parathyroid glands, benign or malignant tumors of the pancreatic islet cells, and peptic ulceration. Multiple endocrine adenomatosis II (Sipple's syndrome or multiple endocrine neoplasia type 2) includes medullary carcinoma of the thyroid, pheochromocytoma and parathyroid hyperplasia, or tumor. The major components of multiple endocrine adenomatosis III are neuroma, medullary thyroid carcinoma, and pheochromocytoma.

All of these syndromes have been described in children. Once one part of a syndrome is identified, a search should be made for the other components. The full-blown clinical picture may take years to develop. Hypersecretion of peptides, amines, or other substances by the neuroendocrine cells are primary markers for the disorders. Hypercalcemia suggests parathyroid dysfunction. Pheochromocytomas produce catecholamines. Increased calcitonin levels are found in medullary carcinoma of the thyroid. Pancreatic islet cell tumors release insulin. Functioning cells that secrete a variety of other compounds have been reported.

Although it is both exciting and frustrating to attempt to keep abreast of the rapid progress in our knowledge, investigators who worked in the 1950s and early 1960s are delighted that methodology is now available to unravel many puzzling clinical problems associated with "functioning tumors."

Elevated Serum Concentrations of Triiodothyronine in Hypothyroid Patients

Values for Patients Receiving USP Thyroid

Robert Penny, MD, S. Douglas Frasier, MD

• **Serum concentrations of thyroxine (T_4), triiodothyronine (T_3), and thyroid-stimulating hormone (TSH) were measured for 14 hypothyroid patients while they were receiving USP desiccated thyroid and after six weeks of therapy with comparable doses of levothyroxine sodium (Na-*l*-thyroxine). Therapy with USP thyroid caused supraphysiologic elevations in the concentration of T_3 in 13 patients. Treatment with levothyroxine resulted in serum concentrations of T_3 that were within the range of normal. We believe the preferable therapy for hypothyroidism is levothyroxine.**

(*Am J Dis Child* 134:16-18, 1980)

Under physiologic circumstances, the thyroid produces two biologically active hormones: thyroxine (T_4) and triiodothyronine (T_3). The major secreted hormone is T_4, and the primary source of circulating T_3 is monodeiodination of T_4 in peripheral tissues, with backflow of T_3 into the blood. If possible, the therapy for hypothyroidism should imitate this normal physiology. Theoretically, this would be accomplished best by the administration of thyroxine alone, and this has been widely recommended.[1,2] Nevertheless, a substantial number of hypothyroid children continue to receive USP desiccated thyroid.[3] This preparation, which is a mixture of T_4 and T_3, has been shown to produce relatively low concentrations of T_4 and elevated concentrations of T_3 in adult hypothyroid patients.[4-6]

For editorial comment see p 130.

We have systematically investigated the effects of therapy with USP thyroid on serum hormone concentrations in hypothyroidism and have compared these with the effects of therapy with levothyroxine sodium (Na-*l*-thyroxine). Our results show that the treatment of hypothyroidism in childhood and adolescence with USP thyroid is unphysiologic.

SUBJECTS AND METHODS

Fourteen hypothyroid subjects, four male and ten female, ages 6.2 to 18.2 years, were evaluated. They were receiving USP (Armour) thyroid in a dose sufficient to maintain their serum T_4 and thyroid-stimulating hormone (TSH) concentrations within the normal range. At the time this investigation was begun, they had been receiving the dose of USP thyroid given in the Table for periods ranging from 2.7 to 13.0 years. All subjects were clinically euthyroid, and their heights and weights were within normal limits throughout the duration of their therapy. Each subject, at the time of a routine clinic visit, had measurements of T_4, T_3, TSH, and the resin T_3 uptake ratio on the same serum sample. Thyroid therapy was discontinued, and they were given replacement therapy with levothyroxine[7,8] at the dose indicated in the Table. Six weeks after the start of levothyroxine therapy, each subject had repeated determinations of T_4, T_3, TSH, and the resin T_3 uptake ratio on the same serum sample. The methods for these determinations have been previously published.[9-13]

Statistical analysis was performed using both the nonparametric Wilcoxon two-sample rank test and the t test.[14] The P values are two-tailed. Within-group variances are indicated as standard deviations (SDs).

RESULTS

As indicated in the Table, the mean serum T_4 concentration was significantly lower when the patients were receiving USP thyroid than when they were taking levothyroxine sodium (7.6 ± 2.0 μg/dL vs 11.7 ± 2.5 μg/dL; $P < .01$). However, all T_4 values were within the normal range for both treatment regimens. The mean serum concentration of T_3 was greatly elevated during therapy with USP

*Normal range, serum: thyroxine (T_4), 4.2 to 15.0 μg/dL; triiodothyronine (T_3), 70.0 to 220.0 ng/dL; thyroid-stimulating hormone (TSH), 0 to 5 μU/mL.
†When compared with mean of appropriate determination by both the Wilcoxon two-sample rank test and the *t* test during therapy with USP thyroid, $P < .01$.
‡Also using the Wilcoxon two-sample rank test and the *t* test, $P > .1$.

hyroid (393 ± 114 ng/dL vs 157 ± 23 ng/dL; $P < .01$). The USP thyroid herapy resulted in great variability n the serum T_3 concentration, and the serum T_3 value was above the range of normal in 13 of the 14 subjects. Serum TSH concentration was adequately suppressed on both treatment regimens, and there was no difference in TSH concentration when the two therapies were compared.

The resin T_3 uptake ratio, which reflects the serum concentration of thyroxine-binding globulin, was within the normal range on both treatment regimens. While patients received USP thyroid, the ratio was 1.0 ± 0.1 (SD), with a range of 0.9 to 1.2. While patients were being treated with levothyroxine, the ratio was 1.1 ± 0.1 (SD) with a similar range of 0.9 to 1.2.

COMMENT

Previous reports have shown that USP thyroid therapy in hypothyroid adults may be associated with elevated serum concentrations of T_3,[4-6] which may exceed the upper limits of the normal range.[5] A similar phenomenon has been recognized in a few children receiving either USP thyroid[10,15] or thyroglobulin (Proloid).[16] Our results, in a systematically studied group of hypothyroid children, confirm and extend these observations.

One possible explanation for the different effects of these two thyroid hormone preparations on the circulating concentrations of T_4 and T_3 is a discrepancy in equivalent dosage. It has recently been shown that a 1-grain (64.5 mg) tablet of USP thyroid contains approximately 64 μg of T_4 and 12 μg of T_3.[17] Thus, 1 mg of USP thyroid contains 1 μg of T_4 and 100 mg contains 100 μg. In addition, biological equivalence of the two preparations averages 1,000:1; ie, 100 mg of USP thyroid is equivalent to 100 μg of levothyroxine sodium.[6] Thus, the doses of USP thyroid and levothyroxine that our patients received were comparable, both in terms of expected T_4 content and average biological activity. The differences that we observed in the circulating levels of thyroid hormones are functions of the preparations themselves and do not result from a discrepancy in dose.

A difference in the source of thyroid hormones in the circulation offers a more likely explanation for these observations. The USP thyroid extract is prepared from animal thyroid glands as an acetone-dried powder that contains both T_3 and T_4. The T_3 content of porcine[18] and human[19] thyroid glands is quite high, and this is reflected in a relatively high T_3 content in thyroid extract tablets.[17] Thus, when thyroid extract is ingested, the source of serum T_4 is gastrointestinal (GI) absorption and the source of serum T_3 is both GI absorption and peripheral conversion from T_4. A substantial proportion of circulating T_3 represents absorbed hormone. Under these circumstances, the level of T_3 in the serum should be higher than if it were only derived from T_4. This latter circumstance characterizes the ingestion of levothyroxine. When this agent is used, circulating T_4 is derived from GI absorption, and circulating T_3 is only derived from peripheral conversion. The level of T_3 should be relatively low. Differences in GI absorption may explain the lower levels of T_4 when ingested as thyroid extract than when ingested as levothyroxine. Individual variability in absorption, as well as the timing of blood samples relative to a dose of medication, probably account for differences in circulating thyroid hormone levels among individual patients.

The elevated concentrations of T_3 that were present in our patients while they received USP thyroid did not lead to any symptoms or signs of hyperthyroidism. This contrasts with the findings of Jackson and Cobb[5] who observed thyrotoxic symptoms in six of 36 hypothyroid adults in whom serum T_3 concentrations were elevated during therapy with thyroid extract. Symptoms were ameliorated when therapy was changed to levothyroxine. Symptoms of hyperthyroidism have also been reported in the cases of two children receiving USP thyroid[10] and in two receiving thyroglobulin.[16] It is curious that only a minority of patients with elevated serum T_3 concentrations, associated with the administration of USP thyroid or thyroglobulin, had thyrotoxic symptoms and/or signs develop. The reason for this is not readily apparent. One possible explanation might be a variable pattern of serum T_3 levels during the 24 hours after the ingestion of USP thyroid. Previous reports indicated that the T_3 elevations seen after the ingestion of USP thyroid may be transient.[4,5] However, we have no data bearing on this point for our patients.

The results of this study show that the administration of levothyroxine sodium in a single daily dosage of 4.2 ± 0.6 (SD) μg/kg mimics the normal physiology of T_4 secretion and T_3 generation. Replacement therapy with USP thyroid in equivalent amounts leads to severely elevated concentrations of T_3 and is unphysiologic. The long-term effects of such superphysiologic concentrations of T_3 in growing and developing individuals is not known. We believe that our data add additional support to the opinion that the therapy for hypothyroidism with USP thyroid should be abandoned.

Sandra Dills and Wilda Lyons provided secretarial assistance.

Elevated Threshold for Thyrotropin Suppression in Congenital Hypothyroidism

Robert M. Schultz, MD; Mark S. Glassman, MD; Margaret H. MacGillivray, MD

• Five infants with congenital hypothyroidism were found to have persistently elevated levels of serum thyrotropin (TSH) for six to 24 months after administration of adequate doses of thyroxine. In these infants, the hypothalamic-pituitary threshold for TSH suppression by thyroxine seems to be unusually high. These observations suggest that serum TSH levels should not be the sole criterion for evaluating adequacy of thyroid hormone replacement during the initial months of therapy for congenital hypothyroidism.

(*Am J Dis Child* 134:19-20, 1980)

Throughout the latter half of pregnancy, there is progressive maturation of the fetal hypothalamic-pituitary-thyroid axis that is independent of the maternal unit.[1] Consequently, newborn infants with congenital primary hypothyroidism exhibit marked increases in levels of thyroid-stimulating hormone (TSH) and low levels of serum thyroxine (T_4). Traditionally, the dose of thyroid hormone administered to these patients has been adjusted by monitoring both the serum concentrations of T_4 and TSH and by standard clinical criteria.

In a recent publication, congenitally hypothyroid children with thyroid maldescent or athyreosis whose conditions were diagnosed between 6 months and 17 years of age were found to require unusually large doses of thyroxine per kilogram of body weight to block the TSH response to thyrotropin-releasing hormone (TRH).[2] This observation suggested that these patients had an unusually high threshold for TSH suppression by T_4. We studied five infants with congenital hypothyroidism, whose ages at time of diagnosis ranged from birth to 4½ months, and who were found to have persistent elevations of serum TSH levels for six to 24 months after the onset of therapy, even though generous doses of thyroxine were administered and the infants were clinically and biochemically euthyroid.

SUBJECTS AND METHODS

The clinical and laboratory data are given in the Table. Serum T_4 and TSH levels were determined by radioimmunoassay. The interassay coefficient of variation for T_4 was 4.0% and for TSH was 11.2%. All patients were treated from the outset with administration of levothyroxine sodium at dosages ranging from 4 to 11 μg/kg of body weight.

A satisfactory clinical response was based on the disappearance of the physical stigmata of hypothyrodism, documentation of a growth spurt, and restoration of serum T_4 concentrations. All patients were clinically and biochemically monitored at two- to four-month intervals during the first 1 to 2 years of life. Without exception, the infants appeared to be euthyroid within one to two months of starting therapy, and all manifested early and continued acceleration of their linear growth rates. Significant improvement was noted in their intellectual and motor skills and, at the most recent evaluation, the developmental quotients in four infants ranged from 92 to 102. Serum TSH concentration remained elevated for as long as six to 24 months after starting thyroid medication, in spite of clinical and biochemical euthyroidism.

COMMENT

The persistent elevation of TSH levels after adequate thyroid replacement in the congenitally hypothyroid infants described in this report suggests that the hypothalamic pituitary system was relatively unresponsive to the negative feedback effect of thyroid hormone. Sato et al reported that higher doses of T_4 are required to suppress the TSH response to TRH in young children with congenital hypothyroidism.[2] With increasing age, the

threshold for feedback regulation of TSH decreases in these children. Taken together, these observations suggest that the threshold for TSH suppression by T_4 is high initially, but that the pituitary-hypothalamic centers become increasingly sensitive to the negative feedback effect of thyroid hormones.

The mechanisms that contribute to the early high threshold for TSH suppression in our patients have not been defined. Subresponsiveness of the hypothalamic-pituitary receptors to thyroid hormone is one possibility. Second, long-standing hyperplasia of the thyrotrophs and persistent hypersecretion of TRH and TSH may require prolonged thyroid replacement to establish a normal equilibrium in the hypothalamic-pituitary axis. Third, the lack of fetal thyroid hormone may influence the number and function of the receptors for thyroid hormone in the regulatory centers of the hypothalamus and pituitary.

From a practical standpoint, these observations indicate that during infancy, serum TSH levels cannot be used as the most accurate indicator of adequate thyroid dose. Therapy must be based on age-adjusted normal concentrations of serum T_4, the growth response, and standard clinical criteria. Altering the dose of thyroid hormone to attain TSH suppression places the infant at risk for overtreatment. Our data support the recommendations of the Committee on Drugs of the American Academy of Pediatrics.[3] These precautions do not apply to hypothyroidism acquired during the childhood or adult years, when TSH suppression is an accurate means of monitoring adequacy of thyroid replacement.[4-6]

This investigation was supported in part by the US Department of Health, Education, and Welfare, Maternal and Child Health Service Project 417, and by the National Pituitary Agency.

Vasoactive Intestinal Peptide Secreting Tumors of Childhood

Saul J. Kaplan; C. Tate Holbrook, MD; Huey G. McDaniel, MD; William L. Buntain, MD; William M. Crist, MD

• **A 2-year-old boy with failure to thrive, watery diarrhea, abdominal distention, hypokalemia, metabolic acidosis, and episodes of hypertension and sweating was found to have a calcified right lower quadrant mass. Blood levels of vasoactive intestinal peptide (VIP) and norepinephrine (NE) were elevated. Presurgical management with phenoxybenzamine hydrochloride and metyrosine was associated with an absence of expected postoperative hypotension, and resection of a benign ganglioneuroma resulted in prompt relief of all symptoms and return to normal of VIP and NE levels. Evidence supports the theory that VIP is the substance responsible for the diarrhea that accompanies some neural crest tumors.**

(*Am J Dis Child* 134:21-24, 1980)

Neural crest tumors account for approximately 8% of all malignant pediatric neoplasms.[1] These patients usually have an asymptomatic abdominal, thoracic, or cervical mass

For editorial comment see p 14.

and excessive catecholamine secretion. A minority have flushing, diarrhea, and/or hypertension secondary to neural hormone secretion. Although diarrhea was ascribed to catecholamine excess in the past,[2] it is now believed that vasoactive intestinal peptide (VIP) is the mediator.[3]

We studied a child with chronic diarrhea, acidosis, and hypokalemia secondary to an abdominal ganglioneuroma that secreted excessive quantities of VIP and catecholamines. Preoperative treatment with specific neural hormone antagonists was performed.

REPORT OF A CASE

A 21-month-old boy was referred for evaluation of watery diarrhea, acidosis, hypokalemia, and abdominal distention of several weeks duration. Physical examination showed a wasted, irritable child with a protuberant abdomen. Blood pressure (supine position) was 80/50 mm Hg. The abdomen was tense and distended, but not tender, and neither ascites nor palpable mass were noted. Height and weight were below the third percentile.

Serum potassium level was 3.0 mEq/L and bicarbonate level was 31 mEq/L. Stools were clay-colored and watery, with a volume of 900 mL/24 hr (1,800 mL/sq m); urinary sodium excretion was 99 mEq/24 hr (normal, 0.5 to 5.0 mEq/24 hr), and potassium excretion was 11 mEq/24 hr (normal, 5.0 to 15.0 mEq/hr). Normal stool trypsin activity, and stool fat, normal glucose, fructose, and sucrose tolerance test results, normal xylose absorption, fat and water-soluble vitamin levels, and sweat chloride determinations were found; and the stools tested negative for reducing substance. A large colon with normal architecture, an enlarged gallbladder, a dilated and kinked right ureter, and nonspecific calcification anterior to the right kidney were identified by roentgenographic techniques.

Diarrhea persisted, even in the absence of oral intake, the serum bicarbonate level fell to 10 to 11 mEq/L, and serum potassium level fell to 2.0 to 2.5 mEq/L. Oral potassium citrate (30 to 50 mEq/24 hr) was given to correct these deficits.

Assay of a 24-hour urine collection showed a vanillylmandelic acid (VMA) level of 68 μg/mg of creatinine (normal, 1.3 to 8.0 μg/mg), a homovanillic acid (HVA)[4] level of 162 μg/mg of creatinine (normal, 4.0 to 23.0 μg/mg), a dopamine level of 4,100 μg/24 hr (normal, 40 to 200 μg/24 hr), and a total catecholamine[5] level of 9.6 μg/mg of creatinine (normal, 0.038 to 0.16 μg/mg). Results of urinary catecholamine fractionation showed 2.3% epinephrine and 97.7% norepinephrine (NE). The serum NE level was 51,000 pg/mL (normal, < 100 pg/mL) and the plasma VIP level was greater than 600 pg/mL (normal, < 80 pg/mL) (Table 1).

Computerized tomography suggested a 4-cm mass anterior to the inferior pole of the right kidney adjacent to the spine (Fig 1). Selective arteriograms were normal, but venography demonstrated a mass partially compressing the inferior vena cava at the level of L-1. Serum NE (venous) value obtained at the level of T-12 was 51,000 pg/mL, and at L-3 was 286,000 pg/mL, suggesting the presence of an intra-abdominal mass not drained by either renal vein (Fig 2).

Because of episodic hypertension (up to 140/100 mm Hg), phenoxybenzamine hydrochloride (an alpha adrenergic blocker), 5 mg orally twice daily, and metyrosine (alpha-methyl-para-tyrosine, a tyrosine hydroxylase inhibitor), 125 mg orally twice daily, were given preoperatively to diminish the possibility of intraoperative hypertension and to avoid postresection hypotension. After five days of therapy with drugs, the urinary total catecholamine level fell (Table 1), and no further episodes of hypertension were noted, but the diarrhea continued.

A small mass was palpated in the midright abdomen with the patient under general anesthesia, and a hard, well-defined, and encapsulated 4-cm tumor was removed from below the right renal vein, adjacent to the inferior pole of the right kidney and right side of the inferior vena cava, and cephalad to the displaced right ureter. Intraoperatively, the patient's blood pressure rose when the tumor was

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

manipulated (from 100 to 140 mm Hg systolic). Blood pressure fell (from 100 to 80 mm Hg systolic) when the mass was removed, but returned to the previous level without intervention within 15 minutes. The tumor was a benign ganglioneuroma. Extract of the tumor mass contained VIP levels at greater than 211 ng/g (> 35,000 pg/mL when corrected for 1:100 dilution).

Postoperatively, an immediate cessation of the diarrhea occurred. Several days after removal, the plasma VIP, urine catecholamines, and plasma electrolyte levels had returned to normal. Four months after surgery, the patient remained healthy without evidence of tumor recurrence.

COMMENT

The association of intractable diarrhea with neural crest tumors in childhood was first described by Hawfield and Daisley in 1952.[8] Subsequently, Rosenstein and Engelman[9] reported a 9% incidence of diarrhea in pediatric patients with neural crest tumors. A similar syndrome in adults with non-β islet cell tumors of the pancreas was described in 1958 and later reviewed in 1974 by Verner and Morrison.[10,11] Since that time, the syndrome of watery diarrhea, hypokalemia, and achlorhydria (WDHA) has been described in adults with pancreatic tumors, pancreatic hyperplasia, bronchogenic carcinoma, hepatic failure, pheochromocytoma, and ganglioneuroblastoma.[6] Vasoactive intestinal peptide is produced by these tumors and is the proposed mediator of this syndrome.[3] It induces increased electrolyte and water secretion by gastrointestinal mucosal cells through stimulation of the adenyl cyclase system.[12] Vasoactive intestinal peptide also causes hyperglycemia, hypercalcemia, inhibition of gastric acid secretion, and profound vasodilatation leading to flushing and hypotension.[11]

Ganglioneuroma and ganglioneuroblastoma are the only tumors reported to produce VIP in children. Eight cases have now been reported and age, sex distribution, histology, location of primary site, blood pressure status, hormone levels, and associated findings are summarized in Table 2. Levels of VIP were elevated in all, but were not as high as those noted in adults. However, tumor tissue levels were comparable.[6] Complete excision was possible and postoperative cessation of symptoms occurred in all but three cases. In one of the unresected cases, the site of VIP production was never found and the child subsequently died of sepsis.[15] A second experi-

enced cessation of diarrhea with partial resection of a ganglioneuroma,[14] and a third died from metastatic ganglioneuroblastoma while undergoing chemotherapy.[18]

Diarrhea is the most common initial complaint in children with VIP-secreting tumors. Hypokalemia and abdominal distention are also frequently found and the hypokalemia is believed to result from massive fecal loss of potassium.[16] These findings are similar to those reported in a review of 18 children with diarrhea and neurogenic tumors in 1963 before the discovery of VIP.[9] Less common signs are failure to thrive and gallbladder distention. Hypercalcemia and glucose intolerance are present in more than 50% of all adults with VIP excess,[11] but similar findings, to our knowledge, are not described in the reported childhood cases.

The catecholamine elevation present in six of the cases reviewed reflects the origin of these tumors from neural tissue. Although concurrent increased secretion of catecholamines and VIP has been reported in an adult with ganglioneuroblastoma,[20,21] catecholamine excess is not generally demonstrated in the more common pancreatic and bronchogenic VIP-secreting tumors.[6,11] The common occurrence of catecholamine excess in children and its rarity in adults with VIP-secreting tumors may explain some of the differences between the presentation of these tumors in these two groups.

Before the discovery of VIP, catecholamines were believed to cause the diarrhea associated with neurogenic tumors.[2,9] However, this hypothesis did not adequately explain why the majority of patients with elevated catecholamine levels have no diarrhea or why some patients with neural crest tumors have diarrhea and normal catecholamine values.[22] It also did not adequately explain why, in a child with watery diarrhea and elevationed levels of both VIP and urinary catecholamines, diarrhea ceased when VIP levels dropped to normal after partial resection of a ganglioneuroma although catecholamine elevation persisted.[14] The summary of present evidence suggests that the diarrhea associated with neural crest tumors is a symptom produced by VIP excess and not by catecholamines.[3,6,12]

Although extensive investigation into the individual effects of VIP and catecholamines has been carried out, there has been little work on the combined effects of these agents. Norepinephrine causes vasoconstriction, whereas VIP is a potent vasodilator. It has been suggested that normotension in some patients with elevations of both hormones is due to these opposing actions.[20,21] However, in cases of VIP elevation alone, hypotension does not usually occur, nor does hypertension always accompany catecholamine excess. In patients with pheochromocytoma, decreased intravascular volume and diminished catecholamine receptor sensitivity are believed to compensate in part during the extreme catecholamine excess and thus avoid continuous extreme hypertension.[23] Consequently, when these tumors are removed and catecholamine levels fall, severe hypotension can occur.

Modlin et al[20] and Taylor et al,[21] describing the same patient, reported near fatal hypotension in an adult after resection of a ganglioneuroblastoma containing both VIP and NE. Intraoperative VIP and NE determination showed more rapid clearance of NE that left a sudden elevation of VIP alone, which corresponded with the onset of hypotension. This is not unlike the hypotension that occurs after resections of a pheochromocytoma. Whether the presence of VIP affects the severity of the hypotension has not been determined.

Our patient had very high levels of NE and intermittently showed signs of catecholamine excess (hypertension

*GN indicates ganglioneuroma; GNB, ganglioneuroblastoma; NR, not recorded.

and sweating). Postresection hypotension was therefore expected due to rapid cessation of catecholamine secretion and transient persistence of VIP in the plasma.[21] To avoid this complication, the patient was treated preoperatively with phenoxybenzamine and metyrosine to reduce pharmacologically the catecholamine levels, block their vasoconstricting actions, and restore intravascular volume.[24] Our patient's blood pressure did not drop preoperatively despite a severe reduction in catecholamine secretion and continued elevation of VIP. The blood pressure, likewise, remained normal after removal of his hormone-secreting tumor. Thus, it appeared that the normal blood pressure in our patient was not simply a result of the balance between these two mediators, but perhaps involved more complex compensatory mechanisms.

The VIP levels in this case fell with administration of metyrosine, although less than did the NE level. Metyrosine is an amino acid analog and may interfere with the synthesis of the tyrosine-containing octocosapeptide VIP. However, catecholamines alone may affect the secretion of VIP, as they are known to stimulate the release of other hormonal products (eg, beta-adrenergic mediated release of insulin). Hence, by diminishing catecholamine levels, VIP release may have been secondarily reduced. In our case, therapy with metyrosine was instituted for only five days prior to VIP measurement. It is likely that longer use of metyrosine could have suppressed VIP levels to the point of diminishing the associated symptoms (ie, diarrhea). Metyrosine is a relatively safe drug whose only untoward effects are sedation (with insomnia on withdrawal), anxiety, tremor, diarrhea, and galactorrhea.[24] A therapeutic trial appears appropriate for any patient with a nonresectable neurogenic tumor and intractable symptoms.

The VIP-producing tumors in children have a somewhat different presentation from the WDHA syndrome as described in adults. Watery diarrhea, hypokalemia, and abdominal distention are common findings. Additionally, symptoms and signs of excess catecholamine secretion such as flushing, increased sweating and hypertension are frequently present. Hyperglycemia and hypercalcemia, although frequently seen in adults with increased VIP secretion, have not been noted in children.

Measurement of VIP should be included in the evaluation of chronic diarrhea after the more usual causes have been ruled out. If VIP level is elevated in a child, a neural crest tumor should be located and removed. Catecholamine levels should also be measured to determine whether preoperative antiadrenergic therapy might be useful. Finally, metyrosine may be useful in the symptomatic treatment of patients with VIP excess.

This study was supported in part by Cancer Center Core grant CA-13148, by a private donation from the Alabama Chapter of the Order of the Eastern Star, and by an American Cancer Society Clinical Fellowship to Dr Holbrook.

Abraham Siegel, PhD, and William McGuffin, MD, and their laboratory technicians provided catecholamine determinations. Vasoactive intestinal peptide levels were determined by Sami I. Said, MD, Dallas. Denise Davis and Henrietta Goodman gave secretarial assistance.

Computerized Tomography in the Evaluation of Isosexual Precocity

Wellington Hung, MD; Gilbert P. August, MD; David R. Brallier, MD; Thomas H. Milhorat, MD

• Clinical and laboratory observations were made in three children with isosexual precocity. None of the patients showed abnormalities in neurological or visual-field examinations although one patient had arrested hydrocephalus and a head circumference greater than the 98th percentile for her age and another patient had a history of seizures. Roentgenograms of the skull were normal in all patients. Cranial computerized tomography (CT) identified a lesion in each patient. We believe that cranial CT should be performed in any patient with isosexual precocity in whom a specific cause is not evident or in whom a cerebral cause is suggested even though the patient may be otherwise normal. Cranial CT is a safe, accurate, and noninvasive technique.

(*Am J Dis Child* 134:25-27, 1980)

The onset of pubertal change prior to 8 years of age in a girl and prior to 10 years of age in a boy is considered to constitute sexual precocity.[1] Although there are many causes to be considered, sexual precocity is not an uncommon sign of an intracranial neoplasm.

Computerized tomography (CT) is a new, safe, and noninvasive roentgenographic technique that has been used to diagnose intracranial abnormalities in infants and children.[2-5] Importantly, CT is without the risks of pneumoencephalography or cerebral angiography.

We describe here three children with isosexual precocity seen during a six-month period, in whom the etiology of the sexual precocity was first detected by cranial CT. Pneumoencephalography and cerebral angiography were used subsequently to further define the lesion and its vascular nature.

REPORT OF CASES

CASE 1.—A boy 6 years and 2 months of age was referred because of pubertal development. He experienced normal development until one year prior to admission when enlargement of the penis and presence of pubic hair were first noted by the parents. Acne and a deepening of the voice had been present for six months. His linear growth from birth to 7 months of age was at the 25th percentile. At 25 months of age, his height was at the 90th percentile. No other growth records were available. The patient had no symptoms referable to the CNS. There was no family history of sexual precocity and there was no history of hormone ingestion.

Physical examination provided the following information: height, 135 cm (greater than the 95th percentile for age); weight, 35.5 kg; blood pressure, 100/60 mm

Blood Hormone Studies

Hormone*	Serum Hormone Values in Cases 1	2	3	Normal Prepubertal Values†
FSH, ImU/mL	5.7	11.2	15	2-11

Hg; and pulse rate, 80 beats per minute. The voice was deep and moderate acne was present on the face. Pubic hair growth and genital development were both Tanner stage 4. Each testis had a volume of 15 mL. The expected testicular volume at this age is between 2 and 4 mL.[4] Neurological and visual-field examinations showed no abnormalities.

Hemogram and urinalysis results were normal. The bone age was 12 years. Roentgenograms of the skull were normal. Results of the patient's hormone studies are given in the Table. The CT scan showed a solid mass that involved the suprasellar cistern (Fig 1), which was not defined further after administration of contrast medium. Angiography confirmed the presence of the mass and the vascular nature of the tumor. Pneumoencephalography demonstrated the mass with its displacement of the surrounding structures.

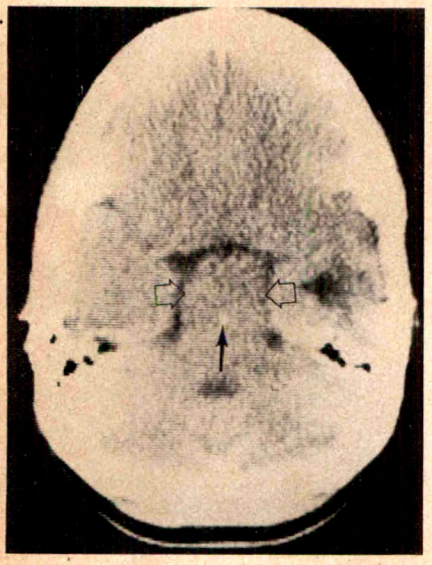

Fig 1.—Solid mass involves suprasellar cistern (open arrows). Basilar artery (solid black arrow) lies directly in front of pons. Normally, there should be CSF (prepontine and suprasellar cisterns) anterior to basilar artery (case 1).

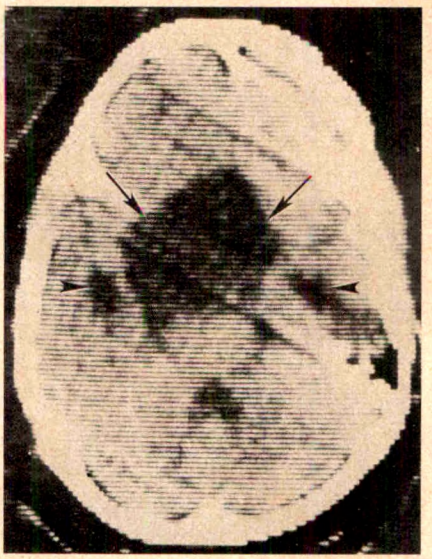

Fig 2.—Large CSF-density cyst (arrows) and mild dilation of temporal horns (arrowheads) (case 2).

Fig 3.—This cut through frontal horns demonstrates that cyst (black arrows) is separated from frontal horns by thin membrane (white arrows) (case 2).

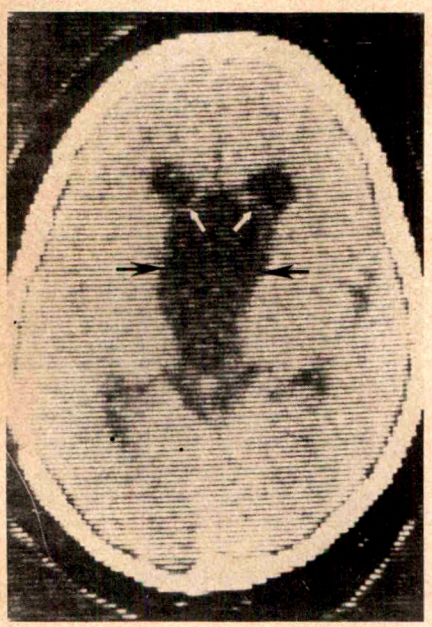

Fig 4.—Cerebrospinal fluid-density suprasellar cyst (arrowheads). Cyst could be confused with third ventricle (case 3).

At surgery, a hypothalamic glioma that originated from the area of the tuber cinereum was found and partially removed. The patient at 7 years and 11 months of age now has a height of 146.4 cm and a weight of 49.8 kg. He is at stage 5 of sexual development. Neurological examination shows no abnormalities.

Case 2.—A girl 5 years and 9 months of age was seen because of seizures and breast development. She was in good health until eight months prior to admission when she experienced her first tonoclonic convulsion. Breast development was first noted at this time. The patient was visiting Washington, DC when she experienced her second convulsion. There was no family history of sexual precocity or of hormone ingestion.

Physical examination provided the following information: height, 111.5 cm (25th to 50th percentile for age); weight, 23 kg; blood pressure, 100/80 mm Hg; and pulse rate, 86 beats per minute. Breast development was Tanner stage 3. No acne or axillary or pubic hair was present. There were no café au lait spots present. The labia minora were pigmented and the vaginal mucosa was pink. On rectal examination, the right ovary was enlarged and the left ovary was barely palpable. Neurological and visual-field examinations showed no abnormalities.

Hemogram and urinalysis results were normal. The bone age was 9 years. Roentgenograms of the skull were normal. An EEG showed an active epileptogenic focus in the left midtemporal area. The results of blood hormone studies are listed in the Table.

The CT scans demonstrated a suprasellar cyst with a density comparable to CSF. Minimal hydrocephalus was also present (Fig 2 to 3). Pneumoencephalography and cerebral angiography confirmed the presence of the mass and showed no evidence of neovascularity.

At surgery, a left temporal arachnoid cyst that extended into the suprasellar area across the midline was found and excised. The patient was lost to follow-up after surgery when she returned to her home in another city.

Case 3.—A girl 7 years and 11 months of age had been followed up for the preceding three years because of arrested hydrocephalus. Breast development had been present

for three months and pubic hair was noted one week prior to referral. There had been no unusual growth acceleration. There was no family history of sexual precocity or of hormone ingestion.

Physical examination provided the following information: height, 141.5 cm (greater than the 80th percentile for age); head circumference, 56 cm (greater than the 98th percentile for age); weight, 39.2 kg; blood pressure, 90/40 mm Hg; and pulse rate, 80 beats per minute. Breast development was Tanner stage 3 and pubic hair growth was Tanner stage 2. The labia minora were pigmented and the vaginal mucosa was pink. The ovaries were not palpable on rectal examination. There was no abnormal cutaneous pigmentation present. Neurological and visual-field examinations showed no abnormalities.

Hemogram and urinalysis results were normal. The bone age was 11 years. Skull roentgenograms were normal. The results of blood hormone studies are given in the Table. The CT scans were similar to those obtained in case 2 except the cyst was smaller and the hydrocephalus was more severe (Fig 4). Cerebral angiography demonstrated that the mass was avascular. Pneumoencephalography demonstrated that the cyst was partially filled with air and thus defined its subarachnoid connection. At surgery, a large suprasellar arachnoid cyst was found and excised.

Menarche occurred at 9 years and 11 months of age and the patient's menstrual periods have been regular. At 10 years and 11 months of age, her height was 156.4 cm and weight was 45.4 kg. She was at stage 4 of sexual development. Results of neurological examination remained normal.

COMMENT

True isosexual precocity is due to premature activation of the hypothalamic-pituitary-gonadal axis that leads to increased circulating levels of the gonadotropins and sex hormones. True isosexual precocity may be separated into "cerebral" and "idiopathic" types.

The cerebral type includes isosexual precocity associated with an identifiable lesion in the brain such as tumor in or adjacent to the hypothalmus, hydrocephalus, or neurofibromatosis.[1] In the absence of an identifiable lesion, the true isosexual precocity is classified as idiopathic. Idiopathic true isosexual precocity is diagnosed by exclusion. True isosexual precocity is more common in girls than in boys, with a sex ratio of approximately 3:1.[5] The idiopathic type is about nine times more frequent than the cerebral type in girls, whereas the ratio is only about 1.5:1 in boys.[5] It should be remembered that in some cases where conditions were diagnosed as idiopathic sexual precocity, there have been cerebral lesions found many years later or detected at postmortem examinations.[6] Therefore, the true incidence of idiopathic isosexual precocity is not known.

Four girls and one boy were studied and their conditions diagnosed as idiopathic isosexual precocity during the six-month period in which our three patients with cerebral isosexual precocity were seen. The incidence of idiopathic vs cerebral type of isosexual precocity based on CT scans in our patients cannot be accurately compared with the incidence reported by Reiter and Kulin[5] because of the small number of patients we saw.

A most difficult differential diagnosis, especially when neurological abnormalities are not evident, is between idiopathic sexual precocity and that owing to an intracranial lesion. Gonadotropin and sex hormone levels are much the same in both types[5] and are, therefore, of no diagnostic help in the differentiation.

We have previously emphasized that pneumoencephalography is mandatory in any boy with isosexual precocity in whom no specific cause can be determined.[7] Pneumoencephalography has been recommended in the evaluation of girls with sexual precocity only if neurological evaluation indicates an abnormality.[5] This suggestion has been made because of the much lower reported incidence of cerebral as compared with idiopathic type of sexual precocity in girls as well as because of the risks of pneumoencephalography.

Based on our experience, we believe that cranial CT is essential in any girl or boy with isosexual precocity in whom no specific cause can be determined or in whom a cerebral cause is suggested. Cranial CT is a safe, accurate, and noninvasive technique and is without the attendant risks of pneumoencephalography or cerebral angiography. The latter two techniques may be necessary to further define the lesion if CT scans show the presence of a lesion.[2]

Pneumonia During Therapy for Childhood Acute Lymphoblastic Leukemia

Stuart E. Siegel, MD; Mark E. Nesbit, MD; Robert Baehner, MD; Harland Sather, MD; G. Denman Hammond, MD

• The incidence of pneumonia was evaluated in 844 children undergoing initial treatment for acute lymphoblastic leukemia (ALL). A total of 310 episodes occurred in 239 patients followed up for five to 36 months after diagnosis. The peak incidences occurred in the periods 0 to 20 days and 40 to 80 days after the start of antileukemic therapy. Bacterial pneumonias occurred primarily during the first 20 days after diagnosis of ALL. No episode of *Pneumocystis carinii* pneumonia was noted before 40 days, and the majority of instances occurred 50 to 120 days after diagnosis. In 80% of all episodes, a specific causative organism was not detected. The incidence of *P carinii* pneumonia was greater in patients receiving intrathecal methotrexate as part of CNS prophylaxis than in those receiving only CNS irradiation. Pneumonia is a frequent event during the therapy of ALL in childhood.

(*Am J Dis Child* 134:28-34, 1980)

Pulmonary infections frequently occur during the therapy of acute leukemia and other malignancies of the hemopoietic system, often resulting in interruption of intensive chemotherapy programs and/or in death.[1-7] According to the literature, pneumonia accounts for 28% to 43% of all fatal and nonfatal infections in these patients.[1,5] Bacterial and fungal organisms comprise more than 90% of all the documented etiologic agents, although viruses and protozoans are recovered more frequently than from normal age-matched patient populations[1-3] and are the most common causes of death due to pneumonia in some series.[6] In addition, the direct pulmonary effects of radiation and specific chemotherapeutic agents, such as methotrexate, have been increasingly implicated in these processes as they are incorporated into standard treatment regimens for acute leukemia.[8-19]

Previous studies of pulmonary disease in acute leukemia have consisted of investigations that stress severe or fatal episodes in relatively small patient populations.[1,2,6,7,20] To determine the frequency and characteristics of pulmonary disease during the therapy of childhood acute lymphoblastic leukemia (ALL) in a large representative population and to identify factors contributing to the development of pulmonary complications, an evaluation was conducted by the Childrens Cancer Study Group (CCSG) as an integral part of an ongoing treatment program for childhood ALL.

SUBJECTS AND METHODS

Patient Population

All patients aged birth to 16 years entered on CCSG protocols 101 and 143 were eligible for this study. Three standard phases of therapy are identified for both protocols: induction, intensification, and maintenance. Protocol CCSG-101 (Fig 1) was designed, in part, to determine the most effective and least toxic means of controlling extramedullary disease in ALL by randomizing patients who attain bone-marrow remission status to one of four intensification regimens, as follow: regimen 1, craniospinal irradiation 2,400 rads and 1,200 rads to an "extended" field that includes total abdomen and pelvis (the testes are included in the pelvic field); regimen 2, craniospinal irradiation 2,400 rads; regimen 3, cranial irradiation 2,400 rads plus methotrexate 12 mg/sq m intrathecally (IT) twice weekly for a total of six doses; and, regimen 4, methotrexate 12 mg/sq m IT twice weekly for six doses only. All patients younger than 18 months of age at the time of diagnosis were assigned to regimen 4. After completion of the intensification phase, a four-drug maintenance program was used, including daily administration of oral mercaptopurine, weekly administration of oral methotrexate, and monthly "pulses" of vincristine sulfate and prednisone.

Protocol CCSG-143 followed this study to test the effectiveness of using a radiation dose of 1,800 rads for CNS prophylaxis. Patients in this study received the same induction and maintenance schedules as those described for CCSG-101, but were

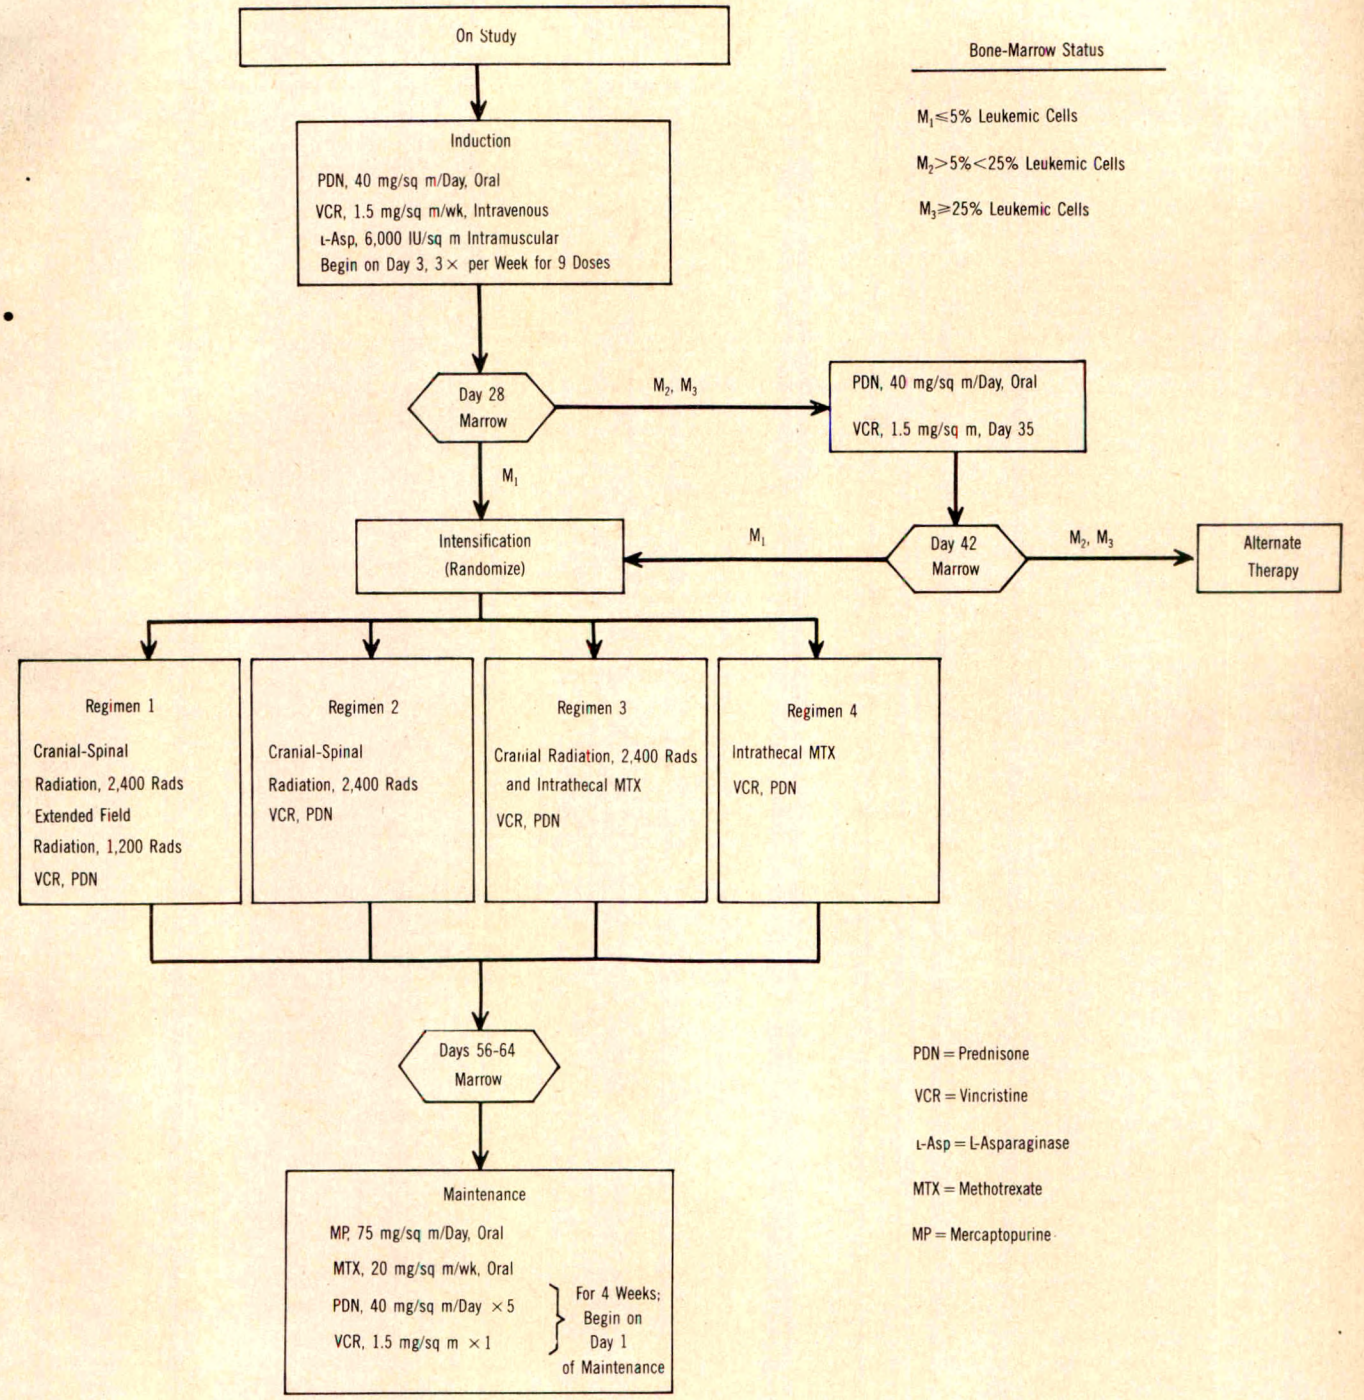

Fig 1.—Therapeutic design for CCSG-101 protocol for acute lymphoblastic leukemia (ALL).

randomized in the intensification phase only to regimens 2 and 3 of CCSG-101. The dose of radiation in both remaining treatment regimens was reduced to 1,800 rads. Infants younger than 18 months of age at time of diagnosis again received IT methotrexate only. Patients were considered "off study" when bone marrow relapse (M_3) occurred or an initial bone-marrow remission (M_1) was not obtained after six weeks of induction therapy. Thus, data presented in this report represent only those events occurring during the initial induction period and first remission of children with ALL.

From June 1972 to February 1975, 844 consecutive patients with ALL were entered on the two treatment programs; 20 institutions in the CCSG were represented. Patients were followed up continually while on study for periods of up to 36 months, with 74% having at least a six-month follow-up and 60% a minimum of a one-year follow-up. For the purpose of the present report, the patient populations of the two studies (CCSG-101 and CCSG-143) were combined and tabulated by intensification regimens. No major statistical differences in identifiable "front-end" prognostic disease variables, such as age and initial WBC count, were noted between the two study groups.

Study Techniques

A detailed questionnaire was completed by investigators at participating institutions on any patient entered on the CCSG-101 or CCSG-143 programs in whom evidence of pneumonia developed. For the purpose of this study, pneumonia was defined as the appearance of a new pulmonary infiltrate on diagnostic roentgenogram accompanied by *one or more* clinical symptom, including fever, cough, tachypnea, cyanosis, and chest pain. Episodes separated by a minimum of seven asymptomatic days were considered to be separate occurrences. Episodes of documented pulmonary embolus were excluded unless proved to be due to infectious agents, such as *Aspergillus* sp. All patients were evaluated for episodes of pneumonia with a complete physical examination and chest roentgenogram. Additional diagnostic studies were performed according to current clinical practices of the participating institution and were not specified in this study protocol.

The questionnaire was designed to determine the clinical, roentgenographic, and laboratory findings accompanying each episode, time of onset in relation to duration of ALL therapy, CNS intensification regimen used, microbiological isolates from diagnostic cultures, clinical course, and ultimate outcome.

Table 1.—Cause of Pneumonia Episodes (N = 310)

Documented Cause	Cases (% of Total)
Bacterial and/or fungal*	
Staphylococcus aureus	8
Streptococcus pneumonia	3
Escherichia coli	4
Pseudomonas aeruginosa	1
Klebsiella sp	1
Aspergillus sp	1
Subtotal	**18 (5.8)**
Viral

Cytomegalovirus	1
Adenovirus	1
Rubeola	2
Subtotal	**8 (2.5)**
Pneumocystis carinii†	22 (6.8)
Interstitial pneumonia	8 (2.6)
Leukemic infiltration	1 (0.3)
Undetermined	248 (80.3)
Not evaluable	5 (1.6)

*Three mixed. infections: one episode each with *E coli* plus *Salmonella* sp; *S aureus* plus *Herpesvirus parainfluenzae*; and, *Klebsiella* sp plus unidentified viral agent.

†Two mixed infections: one episode each with associated E *coli* and *H influenzae*.

Statistical Methods

A computer file was created, using the data abstracted from the pulmonary disease questionnaires, that documented each episode of pneumonia occurring before June 1, 1975. The data in this file were then linked to the basic patient data files maintained for all patients in studies CCSG-101 and CCSG-143. Because patients were under observation for varying periods of time, the method of patient days at risk was used to standardize the majority of the calculated pneumonia incidence rates and comparisons. Life-table comparisons were calculated using the Mantel-Peto-Cox summary χ^2 statistic.[21]

RESULTS

Incidence of Pneumonia

In the 844 patients studied, a total of 310 episodes of pneumonia were noted in 239 patients (28.3%). Of these patients, 186 (78.2%) had one episode, 37 (15.5%) had two episodes, ten (4.2%) had three episodes, and five (2.1%) had four episodes. The overall frequency of pneumonia in this population was 0.87 episodes per 1,000 patient days at risk.

Patients younger than 5 years had a higher incidence (35%) of pneumonia than did those 5 years or older (20%) ($P < .001$). No correlation was noted between the WBC count and/or the presence of mediastinal mass at the time of diagnosis of ALL and the incidence of pneumonia.

Episodes were most common during February and March (1.25 per 1,000 patient days) and at their lowest frequency during July and August (0.65/1,000 patient days). The incidence of pneumonia varied between participating institutions, the range being 0.27 to 1.78 episodes per 1,000 patient days.

Cause of Pneumonia

A specific cause for individual episodes was assigned only if pathogenic organisms were identified in cultures of blood, sputum, or lung tissue, or in histologic sections of lung obtained premortem or postmortem. Cultures of material from upper airway sites, ie, throat or nasopharynx, were not considered adequate for this purpose. The designation of "interstitial" pneumonia was reserved for those episodes in which examination of a lung biopsy specimen showed no specific causative organisms, but did show an interstitial, inflammatory process accompanied by varying degrees of tissue necrosis. Episodes of pneumonia not meeting any of these criteria were classified as of "undetermined" origin.

Table 1 gives the results of these studies. Eighty percent of all episodes were classified as being of undetermined origin. Bacterial and *P carinii* pneumonias predominated in episodes with documented cause. Cases of bacterial or fungal pneumonia were seen at nine of 20 participating institutions, whereas 12 centers reported cases of *P carinii* pneumonia. The distribution of cases with documented cause appeared random. Mixed infections were noted in five cases (Table 1), including two of the 22 cases of *P carinii* pneumonia.

Lung biopsies or aspirations were performed in 53 of the episodes. Thirty were open surgical biopsies and 23 were needle biopsies. A definite causative organism was identified from 20 (66%) of the open-biopsy specimens and from seven (30%) of the specimens obtained by closed proce-

dures. In an additional eight open-biopsy specimens (27%), a histologic diagnosis of "interstitial" pneumonia was made.

Cultures of blood were obtained in conjunction with 174 of the 310 episodes. Pathogens were recovered from the blood in 14 (9%) of such episodes. *Staphylococcus aureus* (five episodes), *Escherichia coli* (four episodes) and *Streptococcus pneumoniae* (three episodes) were the most commonly identified organisms.

Time of Onset of Pneumonia

Figure 2 illustrates the relationship of time of onset of pneumonia to diagnosis of ALL and start of antileukemic therapy. An increased incidence of pneumonia was noted at or within 20 days of diagnosis of ALL. However, the peak incidence of episodes was clearly in the time period of 40 to 80 days after diagnosis. Seventy percent of all first episodes and 63% of all episodes occurred within the first 100 days of therapy. No major interinstitutional variation in this pattern was noted. No relationship was noted between time of onset of pneumonia and age of the patient or the type of CNS intensification regimen used.

Proven bacterial and/or fungal pneumonias occurred primarily in the first 20 days, whereas the majority of cases of *P carinii* pneumonia were noted in the period of 40 to 120 days following initiation of therapy for ALL (Fig 3). No cases of *P carinii* or interstitial pneumonia occurred in the first 40 days. These differences in the relative time distribution of the two etiologic categories are highly significant ($P = .0001$, χ^2 test for a 2×2 contingency table).

Presentation and Pneumonia Episodes

Temperature higher than 38 °C (82% of all episodes) and cough (78%) were the most common symptoms associated with pneumonia in this patient population. Tachypnea (42%) and cyanosis (10%) were less commonly noted. Only 11% of all episodes were accompanied by a recent history of upper respiratory tract infection or pulmonary disease in immediate family members. No relationship be-

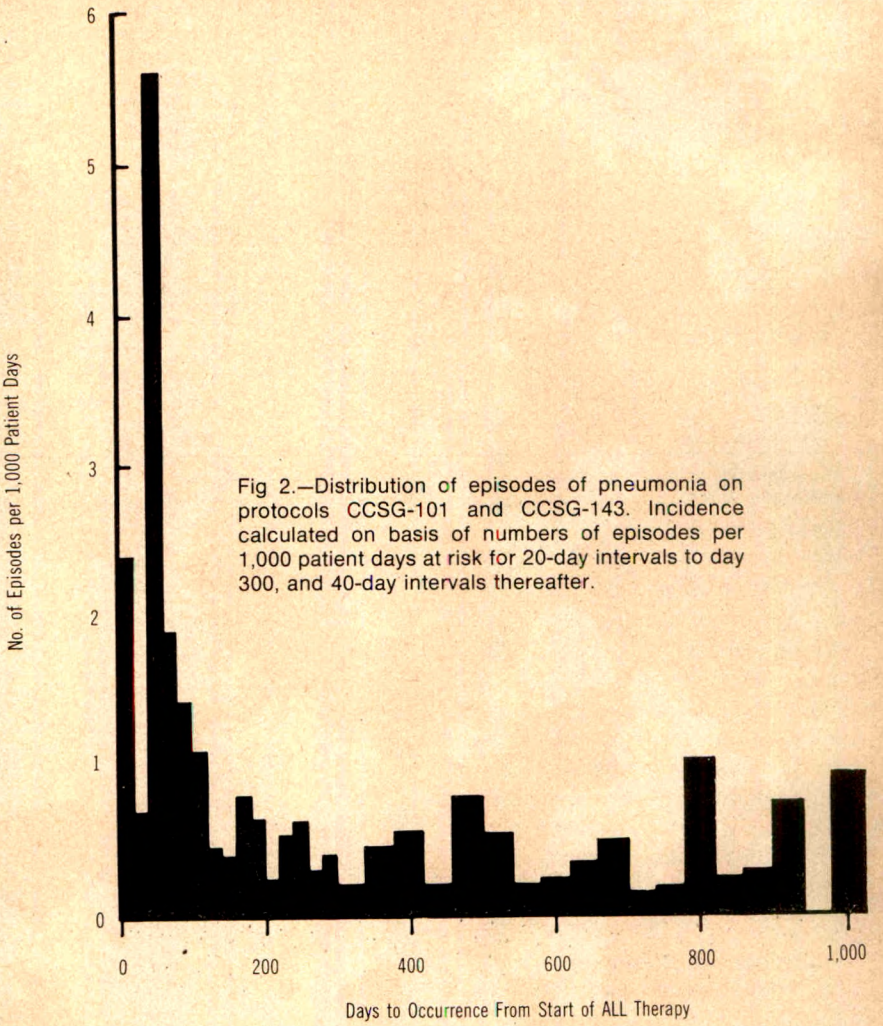

Fig 2.—Distribution of episodes of pneumonia on protocols CCSG-101 and CCSG-143. Incidence calculated on basis of numbers of episodes per 1,000 patient days at risk for 20-day intervals to day 300, and 40-day intervals thereafter.

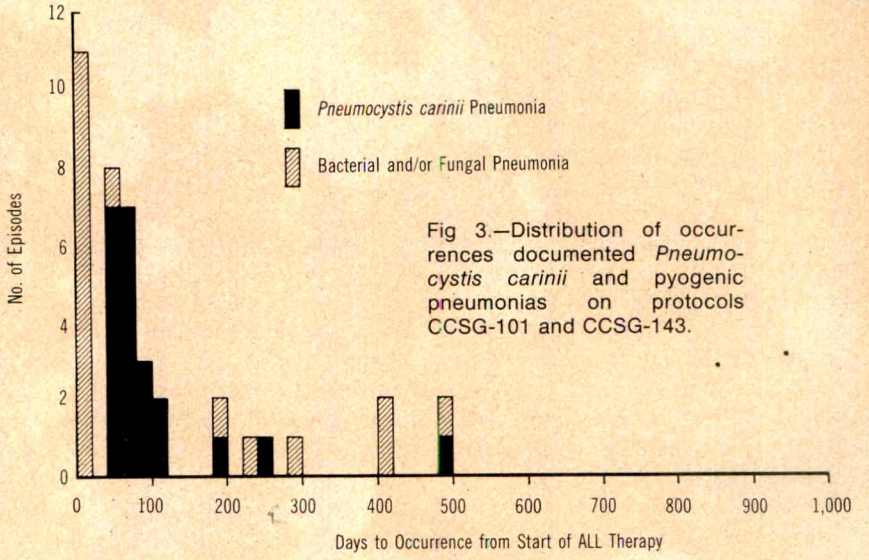

Fig 3.—Distribution of occurrences documented *Pneumocystis carinii* and pyogenic pneumonias on protocols CCSG-101 and CCSG-143.

Table 2.—Intensification Regimen vs Cause and Incidence of Pneumonia*

	Regimen				
	1: Extended Field, Craniospinal Radiation	2: Craniospinal Radiation	3: Cranial Radiation, Intrathecal Methotrexate	4: ≥18 mo of Age At Diagnosis, Intrathecal Methotrexate	4: <18 mo of Age at Diagnosis, Intrathecal Methotrexate
Cause					
Bacterial and/or fungal	3	1	2	1	0
Viral	5	1	1	0	1
Pneumocystis carinii	2	2	8	7	3
"Interstitial"	1	1	2	2	2
Undetermined	37	51	61	53	17
Total episodes (N = 264)	**48**	**56**	**74**	**63**	**23**
Total episodes per 1,000 days at risk	0.72	0.61	0.79	0.80	1.37

*Only episodes on protocols CCSG-101 and CCSG-143 occurring during intensification and maintenance phases (N = 264) are included in this table. The 46 episodes noted during the induction phase are excluded since they could not be affected by the subsequent intensification program.

tween these findings and the cause of the episodes were noted, with the exception of an increased frequency of tachypnea (80%) and cyanosis (45%) in *P carinii* pneumonia. *Pneumocystis carinii* and interstitial pneumonias were more commonly associated with diffuse pulmonary infiltrates on chest roentgenogram (79%), whereas bacterial and/or fungal pneumonias and pneumonias of undetermined cause demonstrated predominantly patchy infiltrates (78%).

Relationship of Pneumonia to Intensification Regimen

Table 2 gives the relationship of the cause of pneumonia occurring *only* during intensification and maintenance phases of therapy to the type of intensification regimen used for these patients. *Pneumocystis carinii* and interstitial pneumonias occurred at a significantly higher frequency in patients receiving intensification regimens 3 and 4 than in those patients receiving regimens 1 and 2 ($P < .01$, life table comparison by summary χ^2 statistic).[21] Children younger than 18 months of age, all of whom had received regimen 4, were excluded from this analysis. The time distribution of cases of *P carinii* pneumonia was similar in regimens 1 and 2 vs regimens 3 and 4 (Fig 4).

No significant differences in *overall* incidence of pneumonia were noted between the four intensification groups. However, patients younger than 18 months of age at the time of diagnosis of ALL, all of whom received IT methotrexate only, had a higher incidence than did older patients.

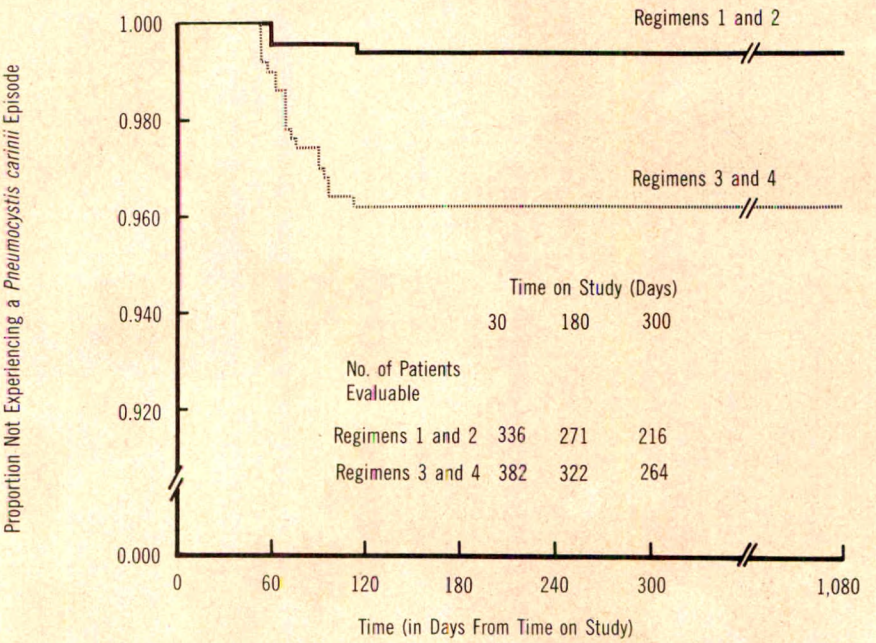

Fig 4.—Relationship of occurrence of proved *Pneumocystis carinii* pneumonia and intensification regimen. Patients were entered in this analysis after competing induction therapy and obtaining a bone-marrow remission.

Relationship of Peripheral Blood Cell Counts at Onset and Cause of Pneumonia

Absolute granulocyte counts less than 500/cu mm were associated with the onset of 49% of all pneumonias that occurred during induction therapy of ALL, whereas only 8% and 20% of all pneumonias in the intensification and maintenance phases, respectively, were associated with this level of granulocytopenia. Nine of 18 episodes of documented bacterial and/or fungal pneumonia occurred in the presence of counts of less than 500/cu mm, whereas only three of 30 episodes of *P carinii* or interstitial pneumonia and 35 of 248 pneumonias of undetermined cause were noted at this level ($P < .0001$) (Table 3). No relationship was noted between the timing or cause of pneumonia and the absolute lymphocyte count, hemoglobin level, or platelet count.

Table 3.—Relationship of Cause of Pneumonitis to Absolute Granulocyte Count at Onset*

Cause, No. of Cases	Absolute Granulocyte Count, cu mm

Course and Outcome of Pneumonia

Eighteen (6.1%) of the 299 episodes in which the outcome was known resulted in death; thus, the overall mortality for pneumonia in this population of 844 patients with ALL was 2.1%, or 0.05 deaths per 1,000 patient days at risk. Nonfatal results were classified by the period of time from diagnosis of pneumonia until complete resolution of symptoms and roentgenographic changes. Patients with roentgenographic infiltrates persisting for more than six weeks accompanied by continued symptoms of pulmonary involvement, ie, cough, fever, or tachypnea, were classified as having chronic disease.

Table 4 indicates the relationship of outcome to cause of the episodes. Approximately 80% of all episodes resolved within three weeks of diagnosis. As expected, mortality was greater for episodes of documented bacterial and/or fungal (33%) and *P carinii* pneumonia (23%) than for those of undetermined cause (2%). Mortality for patients with tachypnea and cyanosis at the time of onset was 40%, but prognosis was not influenced by other signs and symptoms. A higher mortality was noted for episodes occurring in the induction phase of antileukemic therapy (5/42, 12%) than for those occurring in the intensification (8/112, 7%), or maintenance phases (5/155, 3%).

Of the 292 episodes that could be evaluated, seven of 48 (14.5%) with absolute granulocyte counts less than 500/cu mm at time of onset of pneumonia resulted in death, whereas only 11/244 (4.5%) of episodes with counts greater than 500/cu mm ended in death, ($P = .02$, two-sided test of proportions). No relationship between hemoglobin level and platelet count at onset of episodes of pneumonia and outcome of these episodes was detected.

COMMENT

Retrospective studies of large populations of patients with acute leukemia have stressed the relatively low rate of infectious complications in children with ALL compared to adults and to patients with acute nonlymphocytic leukemia.[1,3,4] The present study clearly indicates that pneumonia is a relatively frequent cause of morbidity and, occasionally, mortality during the therapy of childhood ALL. Furthermore, the incidence of pneumonia seen in this pediatric population (0.87 episodes per 1,000 days at risk) is appreciably higher than the 0.1 episodes per 1,000 days at risk reported for all children younger than 5 years of age.[22] Specific data for children 5 years of age and older are not available, but the incidence of pneumonia in this population is estimated to be even lower than that for the younger children.[22,23]

In contrast to previous studies of this phenomenon during the therapy of acute leukemia, patients in the present study were followed up only during their initial remission induction and maintenance therapy courses. Our data, therefore, do not reflect the anticipated increased incidence of infections, including pneumonia, during periods of bone-marrow relapse. The increased incidence of pneumonia observed during early induction therapy (days 0 to 20) is consistent with that from reports in the literature.[1,2] However, the dramatic rise in frequency of pneumonia between days 40 and 80 after initiation of antileukemic therapy reported in this study has not been previously described (Fig 4).

No etiologic agent could be identified in the majority of episodes experienced in this series of patients. Documentation of the cause of episodes often required repeated cultures of blood and open-lung biopsy, particularly for interstitial pneumonias.[24] When a lung biopsy specimen was obtained, a causative organism was identified in 50% of all specimens, a recovery rate that is superior to that reported by Iacuone et al.[7]

Eleven of the 18 bacterial infections occurred during the first 20 days of induction therapy and were associated with severe granulocytopenia.[1,25] In contrast to adults with leukemia,[1,2,7] Gram-positive bacterial pathogens predominated and fungal pneumonia was a rare event. On the other hand, no episode of *P carinii* or interstitial pneumonia occurred before the 40th day of antileukemic therapy, and 25 of the 30 episodes occurred between the 40th and 120th days. These results are similar to those recently reported by

Ruebush et al[26] and Iacuone et al.[7]

The cause of this remarkable increase in incidence of *P carinii* pneumonia at this point in the therapy of ALL, particularly in patients receiving IT methotrexate for CNS prophylaxis (regimens 3 and 4), cannot be clarified in the present retrospective study. In contrast to the report of Iacuone et al,[7] lymphopenia did not play a role in this phenomenon in our patients.[7] Chemotherapeutic agents, particularly methotrexate and corticosteroids, have been shown to cause abnormalities to tissue macrophage function, but further prospective evaluations in children with ALL are necessary to determine if such a mechanism is related to the present findings.[27,28]

The results of this study should encourage the clinician to be aware of the frequency of pneumonia during the therapy of ALL, particularly during the first 120 days of treatment. The high incidence of pneumonias of unknown cause suggest that more vigorous attempts at diagnosis are needed to direct specific therapeutic intervention, particularly for those patients with diffuse interstitial infiltrative findings on chest roentgenogram. Furthermore, the results of this study support a role for early prophylactic therapy for *P carinii* pneumonia as part of therapeutic regimens for ALL.[29]

This investigation was supported by grants to investigators in the Childrens Cancer Study Group, as follows: National Institutes of Health (NIH) grant CA 13539 to Denman Hammond, MD, John Weiner, DrPH, Richard Honour, PhD, Harland Sather, PhD, and James Anderson, PhD, Group Operations Office, University of Southern California Comprehensive Cancer Center, Los Angeles; NIH grant CA 02971 to Ruth Heyn, MD, University of Michigan Medical Center, Ann Arbor; NIH grant CA 03888 to Sanford Leikin, MD, Children's Hospital, National Medical Center, George Washington University, Washington, DC; NIH grant CA 14557 to Denis R. Prevention of Pneumocystis Pneumonia

Use of Continuous Sulfamethoxazole-Trimethoprim Therapy

Richard E. Harris, MD; John A. McCallister, MD; Sari A. Allen; Alexis S. Barton, RN; Robert L. Baehner, MD

• Owing to a 15% attack rate of *Pneumocystis carinii* pneumonitis (PCP) among the leukemic population at Riley Hospital, Indianapolis, a two-year study using continuous low-dosage sulfamethoxazole-trimethoprim to prevent PCP was started in January 1977. A total of 229 pediatric cancer patients considered at high risk for getting PCP received prophylaxis, while 19 additional low-risk cancer patients did not receive sulfamethoxazole-trimethoprim. None of these 248 patients contracted PCP. However, five cases of PCP did occur among ten additional high-risk patients who failed to receive this preparation for a variety of reasons. Complications of the continuous prophylaxis program included neutropenia, rash, and gastrointestinal complaints. This study confirms that continuous, low-dosage sulfamethoxazole-trimethoprim prophylaxis is effective in preventing PCP in susceptible immunosuppressed patients but is ineffective in eradicating the organism from the population at risk.

(*Am J Dis Child* 134:35-38, 1980)

Pneumocystis carinii, a ubiquitous protozoan organism that may reside symbiotically in the respiratory system of man and animals,[1] develops pathogenic potential in immunosuppressed patients.[2] This group includes patients with cancer undergoing chemotherapy or radiation therapy[3,4] and patients receiving immunosuppressives for a variety of disease states.[5-9] In addition, severely malnourished[10] or congenitally immunodeficient patients[11] may have a rapidly progressive and often fatal interstitial pneumonitis owing to this protozoan. Only rarely is PCP found in normal, healthy individuals.[12]

Diagnosis of *P carinii* pneumonitis (PCP) is established by identification of the organism in lung tissue obtained either by open lung biopsy[13] or by percutaneous lung aspirate.[14] The incidence of PCP differs widely among institutions but can be related to the intensity of immunosuppressive therapy.[3] Treatment of PCP with either sulfamethoxazole-trimethoprim[15-19] or pentamidine[20-22] has improved morbidity and mortality from this illness to as low as 5%.[22] Prior to effective treatment, mortality was as high as 100%.

Ideally, an effective program to prevent the development of PCP in immunosuppressed patients would reduce morbidity as well as mortality. Initially, we gave a two-week course of sulfamethoxazole-trimethoprim to susceptible leukemic patients four to six weeks after institution of therapy in an effort to prevent PCP.[23] We observed a delay in the onset of PCP, but our program failed to reduce the high attack rate among our patient population. A prophylactic program for PCP was recently reported from St Judes Hospital[24] and indicated that low-dosage continuous administration of this preparation was effective in preventing PCP in susceptible individuals. The results of this present study confirm the latter observation but point out that such a widespread prophylactic program does not eradicate the protozoan from the patients' environment and is associated with minimal side effects.

STUDY DESIGN

The prophylactic program for PCP consisted of sulfamethoxazole-trimethoprim (Bactrim) at a daily oral dosage of 20:4 mg/kg/day on a twice-a-day schedule. All children with a diagnosis of cancer were entered into the study, but only those who received chemotherapy or extensive radiation therapy from January 1977 to January 1979 were considered to be at high risk and they were the ones who received prophylaxis. Children with cancer who did not receive chemotherapy or who received only radiation therapy to localized areas of the body were considered to be at low risk and did not receive prophylaxis. The projected attack rates for the high-risk group, based on our past experience with children with acute lymphoblastic leukemia (ALL), were 15% and 17%.[3,23] The projected

attack rate was 0% for the low-risk group.

Children with ALL began treatment with the mixture at the start of CNS prophylaxis (day 28) and continued prophylaxis for a minimum of one year. Children with acute nonlymphocytic leukemia (ANLL) and solid tumors began to receive prophylaxis at the start of therapy and prophylaxis was continued for a period six months after all cancer therapy had been stopped.

Parents and patients were informed of the purpose of the study, its potential benefits, and possible side effects; and they were asked to sign a written consent form in accordance with the policies of our institution's Human Investigations Committee before being placed in the prophylactic study. The sulfamethoxazole-trimethoprim was provided in suspension and tablet form. All patients were followed up in the hematology-oncology clinic. Blood levels of trimethoprim were not monitored for each patient, but random samples for sulfa levels supported our clinical impression that compliance was exceptionally good.

REPORT OF CASES

From January 1977 through December 1978, prophylaxis was received by 229 patients, including 110 with solid tumors, 101 with ALL, and 18 with ANLL (high-risk group receiving prophylaxis). The conditions of an additional 19 patients were diagnosed as being solid tumors, but the patients were not placed in the sulfamethoxazole-trimethoprim study because they were not considered at risk for PCP (low-risk group without prophylaxis). Another eight patients (one with ANLL, four with ALL, three with solid tumors) who died early in their courses of therapy were not entered into the prophylactic study. None of these patients had evidence of PCP at autopsy. Review of our pediatric cancer population disclosed ten patients who inadvertently failed to receive prophylactic sulfamethoxazole-trimethoprim. Because of the intensity of their therapy (three with ALL, one with ANLL, six with solid tumors), this group constituted our high-risk group that did not receive prophylaxis (Table).

There were no cases of PCP among the 229 who received Bactrim or among the 19 low-risk patients not receiving prophylaxis. However, among the ten high-risk patients who inadvertently failed to receive the preparation, five cases of PCP were encountered. Their case histories follow:

Results of *Pneumocystis carinii* Pneumonitis (PCP) Prevention Study

Group	No. of Patients*				Contracted PCP
	ALL	ANLL	Solid Tumors	Total	
Prophylaxis, high-risk	101	18	110	229	None
No prophylaxis, low-risk	0	0	19	19	None
No prophylaxis, high-risk	3	1	6	10	5†
Died too soon	4	1	3	8	None

*ALL indicates acute lymphoblastic leukemia; ANLL, acute nonlymphocytic leukemia.
†Includes three with ALL, one with ANLL, and one with a solid tumor.

Case 1.—A 3-year 5-month-old boy was referred to Riley Hospital, Indianapolis, in December 1977 with suspected leukemia. A diagnosis of null cell ALL was made by bone marrow aspiration and he was placed on the Children's Cancer Study Group protocol 141A with a 28-day induction program of vincristine sulfate, prednisone, and asparaginase, CNS prophylaxis consisting of 2,400 rads of cranial radiation, six doses of intrathecal methotrexate sodium, and daily oral mercaptopurine, followed by a maintenance regimen with monthly vincristine-prednisone pulses, daily mercaptopurine, and weekly methotrexate. Because of a low red cell glucose-6-phosphate dehydrogenase (G6PD) level at diagnosis, the patient was not given sulfamethoxazole-trimethoprim. On April 18, 1978, he was admitted with fever, tachypnea, hypoxia, and bilateral patchy interstitial infiltrates on his chest roentgenogram. Examination of the open lung biopsy specimen disclosed PCP, and he rapidly responded to a ten-day course of intramuscular (IM) pentamidine at 4 mg/kg/day. Even though repeated G6PD levels at this time still were borderline low, he was given a trial of low-dosage sulfamethoxazole-trimethoprim after recovery from PCP, and hemolysis failed to develop. He has remained well to date with prophylaxis.

To prevent recurrence of PCP, it has been our policy to begin continuous low-dosage prophylaxis on full recovery from the pneumonitis. Recurrence of PCP in two patients who did not receive such prophylaxis has recently been reported by Tebbi.[25]

Case 2.—A 5-month-old female infant referred to Riley Hospital in the autumn of 1976 for anemia (hemoglobin level, 6.0 g/dL) and leukocytosis (WBC count, 157,000/cu mm). On admission, a bone marrow aspiration revealed null cell ALL; she received a 28-day induction course consisting of vincristine, prednisone, and asparaginase. She had CNS leukemia at the end of the otherwise successful induction and received six doses of intrathecal methotrexate along with 2,000 rads of cranial radiation during the ensuing four weeks. The lymphoblasts cleared from the spinal fluid. She was one of the last patients to be placed in our previous PCP prophylactic study. She received a two-week course of either sulfamethoxazole-trimethoprim at 100:20 mg/kg/day or placebo beginning on day 28. In January 1977, we began the present prophylactic study and gave all patients still receiving therapy and all patients with newly diagnosed conditions continuous low-dosage sulfamethoxazole-trimethoprim. This patient was overlooked until the 66th day after diagnosis of ALL when she had fever, tachypnea, hypoxia, and interstitial infiltrates on her chest roentgenogram. Examination of an open lung biopsy specimen showed PCP. She was treated with IM pentamidine at 4 mg/kg/day for ten days and recovered uneventfully. When the code of the double-blind study was broken, it was discovered she had received the placebo. She subsequently received sulfamethoxazole-trimethoprim prophylaxis but sustained a bone marrow relapse in September 1977 and died in October 1977.

Case 3.—The patient, a male infant, was referred in May 1977 at 4 months of age for bilateral axillary and inguinal lymphadenopathy. The node biopsy specimen indicated histiocytosis-X and further evaluation showed radiolucencies in the right anterior maxilla and the left mandibular alveolar ridge. He was placed on a regimen of daily oral prednisone and weekly intravenous (IV) vinblastine sulfate, with subsequent great decrease in the lymphadenopathy. By oversight, he was not placed in the PCP prophylactic study. In July 1977, he had tachypnea, hypoxia, and fever. An open lung biopsy specimen showed PCP, and his condition was treated with sulfamethoxazole-trimethoprim at 100:20 mg/kg/day orally for 14 days while his prednisone dosage was tapered. The infection quickly cleared, but he had a diffuse, fine, erythematous maculopapular rash while receiving Bactrim. The rash desquamated and then cleared after discontinuance of prophylaxis with the mixture. The open

lung biopsy specimen also showed pulmonary involvement with histiocytosis-X. Based on this observation, his chemotherapy was subsequently changed to a more aggressive program consisting of vinblastine, prednisone, cyclophosphamide (Cytoxan) and methotrexate. At the present time, he has no evidence of active histiocytosis-X. He has not been given prophylaxis with sulfamethoxazole-trimethoprim again because of the rash he had while receiving the antibiotic.

CASE 4.—This female patient was referred in March 1977 at age 3 years and 2 months for evaluation of fever, pallor, and petechiae. Bone marrow examination revealed acute monocytic leukemia, and she was given an induction regimen consisting of daunorubicin hydrochloride, vincristine, prednisone, azacitidine, and cytarabine (cytosine arabinoside). She achieved a marrow remission, but her induction phase was complicated by measles. She inadvertently failed to receive sulfamethoxazole-trimethoprim prophylaxis. In June 1977, she had fever, tachypnea, hypoxia, and diffuse interstitial infiltrates. Her open lung biopsy specimen indicated PCP that rapidly responded to pentamidine at 4 mg/kg/day for ten days. She was subsequently given sulfamethoxazole-trimethoprim continuous prophylaxis and remains in remission at the present time while receiving monthly courses of vincristine, azacitidine, cytarabine, and oral thioguanine.

CASE 5.—A 3-year 2-month-old girl was referred to Riley Hospital on Sept 19, 1978 for fever, epistaxis, and ecchymoses. A bone marrow aspiration showed null cell ALL and she was placed on a 28-day induction program consisting of vincristine, prednisone, and asparaginase and six weekly doses of intrathecal methotrexate. Central nervous system prophylaxis was continued at 3-month intervals with intrathecal methotrexate (in lieu of cranial radiation). Maintenance therapy consisted of daily oral mercaptopurine and weekly oral methotrexate. Because she did not receive cranial irradiation or monthly vincristine-prednisone pulses, it was decided not to give her sulfamethoxazole-trimethoprim prophylaxis. On Nov 4, 1978, she had cough and fever, and a chest roentgenogram indicated a right middle lobe infiltrate. She was given a ten-day course of oral amoxicillin trihydrate, but she failed to respond. Thus, she was hospitalized, treated with IV ampicillin sodium, and given low-dosage sulfamethoxazole-trimethoprim (20:4 mg/kg/day) prophylaxis. Two days later, she was discharged on a regimen of oral amoxicillin and sulfamethoxazole-trimethoprim. However, four days thereafter, she again had fever and mild respiratory distress and was readmitted to the hospital on Nov 20, 1978. The sulfamethoxazole-trimethoprim and amoxicillin therapies were discontinued, and she was observed. She had tachypnea, hypoxia, and rapidly progressive interstitial infiltrates. Study of an open lung biopsy specimen on Nov 22, 1978 revealed PCP. She was again given Bactrim at a dosage of 100:20 mg/kg/day and experienced extremely rapid improvement. After a 14-day course of this mixture, she was given its low prophylactic dosage, which she continues to take at present.

Patient 5 is also of special interest because her case history demonstrates that low-dosage prophylaxis with sulfamethoxazole-trimethoprim (20:4 mg/kg/day) may not cure an already clinically infected host, whereas a higher dosage of this preparation (100:20 mg/kg/day) usually will.

COMPLICATIONS OF PROPHYLAXIS

Rash

Among the 229 patients given sulfamethoxazole-trimethoprim prophylaxis, five had rashes owing to this preparation, and three others had a rash possibly owing to the use of this mixture, for an incidence of 3.5%. One patient had hives directly attributable to Bactrim because of its rapid reoccurrence on rechallenge with this mixture. Another child had Stevens-Johnson syndrome owing to this preparation and recovered after withdrawal of the drug and a short course of prednisone at 2 mg/kg/day. The other patients with rash had fine, diffuse maculopapular erythematous lesions generally associated with mild pruritis. In two of these patients, the rash was associated with mild pruritis. In two of these patients, the rash was associated with eosinophilia.

Gastrointestinal (GI) Effects

Three patients were suspected of having nausea and vomiting in association with sulfamethoxazole-trimethoprim usage (incidence, 1.3%). When treatment with the drug was discontinued, the nausea and vomiting ceased. However, none of the patients experienced GI discomfort on rechallenge with this combination at a later date.

Neutropenia

Because of concomitant chemotherapy or radiation therapy, neutropenia induced by sulfamethoxazole-trimethoprim usage was difficult to prove in most cases. However, neutropenia was well documented to be due to this preparation in five patients, and the drug was suspected to be possibly contributing to neutropenia in six other patients (incidence, 4.8%). All well-documented cases showed resolution of the neutropenia when prophylaxis with this mixture was discontinued even though chemotherapy was continued. A typical case history follows:

A 6-year 10-month-old boy was referred in January 1977 for evaluation of a left chest wall mass. A biopsy specimen of the mass showed Ewing's sarcoma. He was initially treated with vincristine, cyclophosphamide, and doxorubicin hydrochloride (Adriamycin) to reduce the size of the mass. Irradiation therapy was begun in March 1977 to further reduce the mass prior to complete surgical resection carried out in May 1977. Since then, he has continued to receive multiagent chemotherapy, with no evidence of recurrence. Sulfamethoxazole-trimethoprim prophylaxis was started at the time of diagnosis. During his maintenance cycles of weekly IV cyclophosphamide and vincristine, he had many delays and reductions in dosage of chemotherapy owing to neutropenia. On June 6, 1978, sulfamethoxazole-trimethoprim prophylaxis was discontinued on the suspicion that it was contributing to his neutropenia, but the chemotherapy was continued. The next week, his absolute granulocyte count increased from 650 to 3,400/μL, and since then, he has been able to tolerate full-dosage chemotherapy with no delays.

COMMENT

For several years, our institution has experienced an unusually high (15% ± 7%) attack rate of pneumocystis pneumonitis among its immunosuppressed leukemic population.[3,23] Similar epidemics had previously been encountered in the same population at other institutions.[26,27] In 1975, an investigation at Riley Hospital by the Center for Disease Control,[3] Atlanta, suggested that transmission of pneumocystis was occurring within the hospital environment since the hospital staff with close contact with the susceptible patients had a higher

prevalence of elevated antibody titers than other staff members. In addition to the leukemic population, a systematic diagnostic approach to cases of interstitial pneumonitis in patients with solid tumors also frequently identified PCP.[13]

In an attempt to reduce the attack rate among the entire cancer population, children at risk for PCP were treated with a two-week course of sulfamethoxazole-trimethoprim at a dosage of 100 and 20 mg/kg/day of sulfamethoxazole and trimethoprim, respectively. The results of the institutional study showed that the prophylaxis did not decrease the attack rate but only delayed the occurrence of the pneumonitis by about four months.[23]

Because of the failure of the two-week, full-dosage course of this mixture to prevent PCP, the present study was started in January 1977. Hughes et al[24] had shown that low-dosage (20:4 mg/kg/day) sulfamethoxazole-trimethoprim prophylaxis continued throughout the period of cancer therapy totally prevented PCP. Our study confirmed this prior observation since none of the 229 patients who received continuous prophylaxis had PCP. Of importance were the five cases of PCP developing among the ten patients who were at risk but failed to receive this preparation. This observation demonstrates the continued presence of the protozoan in the environment and its failure to be eradicated by the prophylactic program. This study does not prove that the drug did or did not eradicate the organism from treated patients. On termination of prophylaxis with the drug, new organisms could have been acquired from exogenous sources. This study also points out the extreme effectiveness of sulfamethoxazole-trimethoprim in prevention of PCP. As noted in patient 5, successful treatment of PCP requires the higher dosage since the protozoan remained in the lung of the patient receiving the lower dosage of this mixture for a full week. Side effects from the preparation encompassed a variety of rashes, neutropenia, and occasional GI complaints. However, these side effects must be weighed against its effectiveness in prevention of PCP in these high-risk patients.

This work was supported in part by grants from The Riley Memorial Association, Indianapolis; and Clinical Fellowship grant 3769 of the American Cancer Society, Indianapolis.

The drug sulfamethoxazole-trimethoprim was supplied by the Hoffmann-LaRoche Co, Nutley, NJ.

Theophylline Toxicity in Term Infants

F. Estelle R. Simons, MD; Frank R. Friesen, MD; Keith J. Simons, PhD

• The pharmacokinetics of theophylline were studied in 1-month-old term infants who received accidental overdoses of theophylline during treatment for bronchiolitis. Both infants survived without neurologic sequelae. Elimination half-life values of 14.5 and 15.2 hours, respectively, were shorter than reported in premature infants but longer than in infants aged 3 months or older. Caffeine appeared in the sera of both patients, who had not received it in any form. In term infants, elimination of theophylline may occur by *N*-methylation in contrast to older patients in whom the drug is chiefly eliminated by demethylation and oxidation. Theophylline has not been proved effective for the treatment of bronchiolitis. It should be used with caution for wheezing in very young infants until its pharmacokinetics have been studied further in nontoxic, full-term infants younger than age 3 months.

(*Am J Dis Child* 134:39-41, 1980)

The pharmacokinetics of theophylline in term infants have not been reported to date, to our knowledge. We studied the pharmacokinetics of the drug in term infants aged 4 and 5 weeks who were referred to us after accidental administrations of toxic doses of theophylline by the intravenous (IV) route for treatment of bronchiolitis.

REPORT OF CASES

CASE 1.—A 5-week-old, 3.7-kg infant who was delivered at term was hospitalized because of wheezing, coughing, cyanosis, and respiratory distress. An IV loading dose of 6.25 mg/kg of aminophylline was administered and was followed by a continuous infusion of 15 mg/kg/24 hr. Inadvertently, 15 mg/hr was infused over nine hours, at which time jitteriness and tachycardia were noted. The serum theophylline concentrations are shown in Fig 1. Levels of glucose and protein in the CSF and a cell count of the CSF were normal, as were blood glucose and serum electrolyte levels and the results of liver function tests. The serum albumin concentration was 4.3 g/dL.

The respiratory rate increased despite diminished respiratory distress and the disappearance of wheezing. During the next 24 hours, sinus tachycardia (heart rate, 182 to 220 beats per minute) was noted. The infant vomited, retched, and passed ten loose stools from which no pathogens were cultured. Wakefulness, jitteriness, intermittent clonic posturing of the legs and arms, ankle clonus, and hyperreflexia were noted during this time, but seizures did not occur. The infant recovered uneventfully.

CASE 2.—Infusion of 15 mg of aminophylline over half an hour was prescribed for a 4-week-old, 3.9-kg infant who was delivered at term and who had bronchiolitis. In error, 15 mL (750 mg) was given. A generalized tonoclonic seizure occurred 45 minutes later. On admission to the Children's Centre Hospital, Winnipeg, Manitoba, Canada, six hours after the overdose, the baby was hyperalert and tremulous, with unsustained ankle clonus and brisk deep tendon reflexes. There were no localized neurologic signs. Respiratory distress, diminished air entry, and cyanosis were present, but wheezing was not detectable. Retching occurred intermittently, and nasogastric tube suction yielded "coffee ground-like fluid." Sinus tachycardia (188 to 230 beats per minute) persisted for 60 hours.

The serum theophylline concentrations are shown in Fig 2. Serum values were as follows: sodium, 125 mEq/L; potassium, 2.8 mEq/L; and glucose, 370 mg/dL. The specific gravity of the urine was 1.031, and ketones and 170 mg/dL of glucose were present. The results of liver function tests were normal. The serum albumin concentration was 3.4 g/dL. The CSF cell count and protein and glucose levels were normal.

In the first 24 hours after admission, despite correction of the hyponatremia, five episodes of opisthotonic posturing and tonoclonic movements occurred. These were treated with 0.3 mg/kg of diazepam. On the EEG, spike and wave complexes were observed over the right and left frontocentral areas. Seizures increased in frequency 24 hours after the overdose and were treated with 10 mg/kg of IV phenobarbital sodium followed by 2.5 mg/kg every 12 hours and with 20 mg/kg of phenytoin sodium followed by 3 mg/kg every 12 hours. The serum concentrations of these drugs were 23 μg/mL and 21 μg/mL, respectively, and an EEG was normal 48 hours after the overdose. Chewing movements, eye blinking, nystagmus, staring, and deviation of the eyes continued for another 24 hours.

Wheezing recurred 60 hours after the overdose, but it resolved gradually. No respiratory, cardiac, or neurologic abnormalities were detected at discharge from the hospital.

ANALYTICAL METHODS

Theophylline and caffeine concentrations in the serum, CSF, and urine were measured by high-performance liquid chromatography.[1] The presence of caffeine was confirmed by mass spectrometry. Theophylline protein binding was measured by an ultrafiltration technique.[2]

DATA ANALYSIS

Log serum theophylline concentrations were plotted vs time.[3] Linear portions of the data were fitted to equation 1:

$$\ln Cp(t) = \ln Cp(o) - Kt, \qquad (1)$$

where $Cp(t)$ is the serum concentration at any time t, $Cp(o)$ is the serum concentration extrapolated to time zero, and K is the first-order elimination-rate constant. The serum half-life ($t_{1/2}$) was calculated using equation 2:

$$t_{1/2} = 0.693/K. \qquad (2)$$

Protein-binding values ($\beta\%$) were calculated using equation 3:

$$\beta\% = [(Dt - Df)/Dt] \times 100, \qquad (3)$$

where Df and Dt are the theophylline concentrations in the filtrate and retained material, respectively.

RESULTS

Plots of the log serum theophylline concentrations vs time were constructed for each infant (Fig 1 and 2). Serum theophylline concentrations one hour after the overdose were 76.5 μg/mL in patient 1 and 182 μg/mL in patient 2. In patient 1, the theophylline elimination half-life was 14.5 hours. In patient 2, it was 15.2 hours during the first 30 hours after theophylline overdose, but it decreased to 8.5 hours 40 hours after phenobarbital administration (that is, from 65 to 100 hours after the overdose).

In patient 2, serum and CSF theophylline concentrations at 24.5 hours were 73.6 μg/mL and 47.6 μg/mL, respectively, and at 45.4 hours, 38.2 μg/mL and 23.4 μg/mL, respectively. At 45.4 hours, the serum theophylline concentration in the sagittal sinus was 37.4 μg/mL. In patient 1, the theophylline protein-binding values were 66% and 62% at serum theophylline concentrations of 60.0 and 31.2 μg/mL, respectively. In patient 2, the theophylline protein-binding values

were 53.4% and 68.7% at serum theophylline concentrations of 76 μg/mL and 10.7 μg/mL, respectively. The serum albumin concentrations were normal for patients of this age.

Although the infants were not breast-fed and did not receive caffeine in any form at any time after birth, the serum caffeine concentration in patient 1 was 2.4 μg/mL in two pooled samples that contained 60.0 and 31.2 μg/mL of theophylline. In patient 2, serum caffeine concentrations were 0.9 μg/mL one hour after the overdose and 10.8 μg/mL 42 hours after the overdose, when serum theophylline concentrations were 182 and 40 μg/mL, respectively (Fig 2). In a urine sample collected 45 hours after the theophylline was administered, 7.9 mg of theophylline and 0.25 mg of caffeine were found.

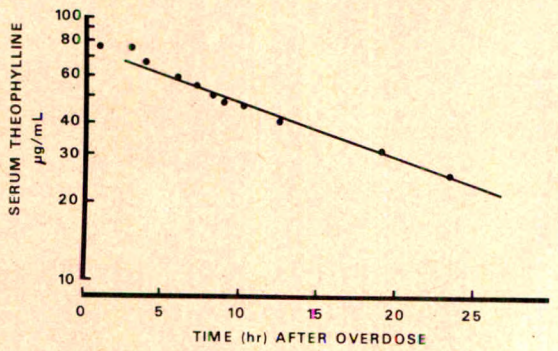

Fig 1.—Serum theophylline concentrations vs time for patient 1 at age 5 weeks. Half-life of theophylline was 14.5 hours.

COMMENT

The toxic effects of theophylline include tachycardia, other cardiac arrhythmias, hypotension, hypertension, insomnia, irritability, nervousness, tremor, convulsions, nausea, vomiting, gastrointestinal bleeding, loose stools, hyperthermia, albuminuria, and dehydration.[4] In infants, ketosis,[5] prolonged diuresis,[6] paroxysmal supraventricular tachycardia,[7] and hyperglycemia[5,8] have occurred. Both the clinical symptoms of toxicity and the lethal dose may differ according to the patient's age and ability to metabolize the drug.

Adults have had seizures and died without preceding minor symptoms (such as nausea) when serum theophylline concentrations were only 25 to 70 μg/mL. Some of these patients had abnormal hepatic function with probable low serum albumin concentrations, diminished theophylline protein binding, and excellent penetration of the drug into the CNS.[9] In an adult with hepatic failure, intractable seizures occurred when the CSF theo-

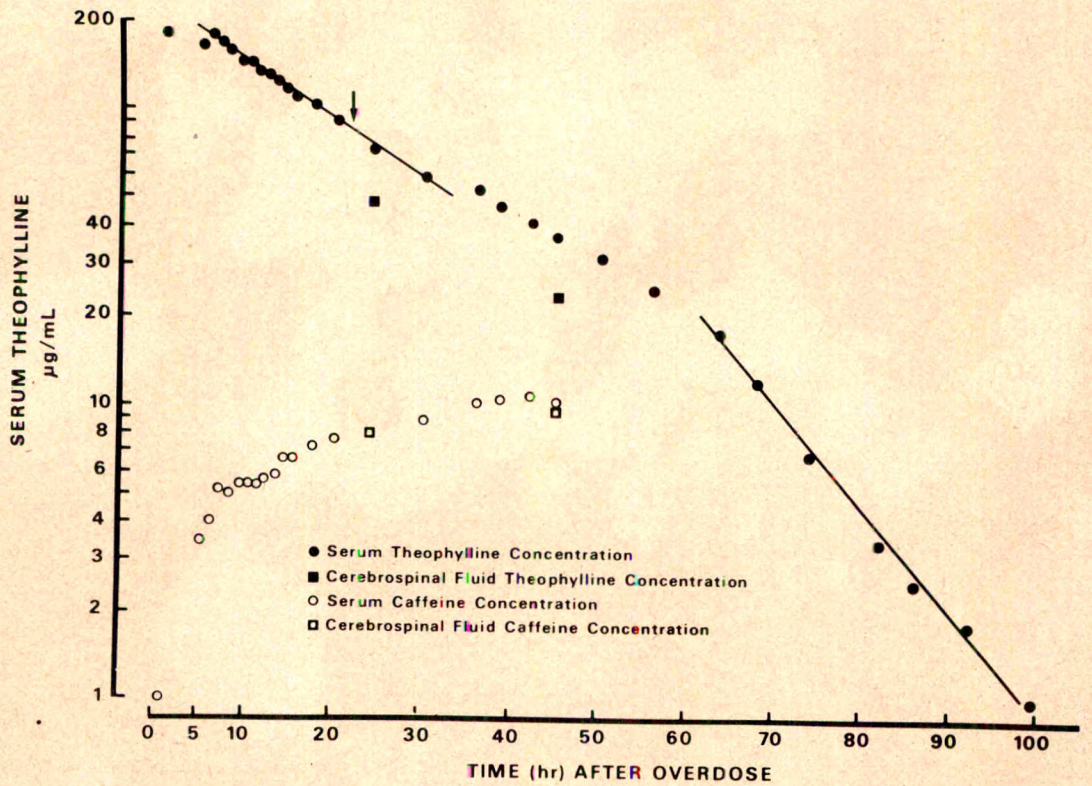

Fig 2.—Serum theophylline concentrations, CSF theophylline concentrations, and serum and CSF caffeine concentrations vs time for patient 2 at age 4 weeks. Half-life of theophylline was initially 15.2 hours, but then decreased to 8.5 hours. Arrow indicates commencement of phenobarbital therapy.

phylline concentration was 37 μg/mL compared with 40 μg/mL in the plasma.[10] Theophylline protein binding, although not measured directly, may have been diminished,[11] as serum albumin had been 2.6 g/dL.

On the other hand, in young children, survival after theophylline toxicity has been reported with a serum concentration of 141 μg/mL.[5] In our patient 2, who survived with a serum concentration of 182 μg/mL, CSF concentrations (Fig 2) were 60% to 63% of the serum concentrations, and the theophylline protein-binding value was in the normal range.[2] As serum theophylline concentrations decreased from 80 to 40 μg/mL, the seizures became more frequent despite additional treatment with anticonvulsant medication. This suggests that the lowered seizure threshold in the CNS of young infants may be associated with a critical range of theophylline concentrations above and below which seizures do not occur.

In adults with theophylline poisoning, serum concentrations have been lowered rapidly by hemodialysis using a resin[10] or charcoal[12] filter, but not all treated patients have survived.[10] In the infants described here, hemodialysis and exchange transfusions were not performed because serious signs of toxicity such as severe arrhythmias, cardiorespiratory collapse, or coma did not occur. In the first infant, seizures were not present, and in the second infant, they were readily controlled with anticonvulsants.

Dose-dependent theophylline pharmacokinetics have been observed in children with asthma who were given sequential aminophylline infusions and in one patient who received a 50% overdose and had initial theophylline concentrations of about 80 μg/mL.[13] In our patient 1, who had an initial serum theophylline concentration of 76.5 μg/mL, the plot of log serum concentrations vs time was linear, so dose-dependent kinetics were not observed (Fig 1).

The half-life values in these 1-month-old infants were long compared with those of infants aged 3 to 23 months in whom the mean half-life was 4.4 hours, which is similar to the half-life in young children.[14] However, the half-life values were shorter than in premature infants who were treated with theophylline for apnea.[15-17]

In patient 2, over a range of serum theophylline concentrations of 180 to 60 μg/mL, the plots of log concentrations vs time were also linear (Fig 2), indicating the absence of dose-dependent kinetics. The scatter in the data between serum concentrations of 60 and 18 μg/mL may be due to the administration of IV fluids and changes in the volume of distribution, to spontaneous enzyme induction, or to the enzyme-inducing effect of the phenobarbital that was administered from 22 hours after the overdose. After 40 hours of treatment with phenobarbital, the plot of log theophylline concentrations vs time again became linear, with a half-life of 8.5 hours, which was 50% of the initial value. Pretreatment with phenobarbital may[18] or may not[19] enhance theophylline elimination in adult humans.

In adults, theophylline is demethylated and oxidated in vivo to 3-methylxanthine, 1,3-dimethyluric acid, and 1-methyluric acid (20), and methylation to caffeine (1,3,7-trimethylxanthine) does not occur. However, in premature neonates, methylation of theophylline at the N-7 position has been demonstrated.[21] This study confirms the fact that large doses of theophylline are also metabolized to caffeine in 1-month-old term infants as shown by increased serum caffeine concentrations that were measured by high-performance liquid chromatography and mass spectrometry. In addition, methylation may be a slower first-order metabolic pathway that masks any dose-dependent kinetics in these infants who received overdoses.

Theophylline has not been objectively evaluated in the treatment of wheezing in young infants. In our patients, wheezing disappeared at very high serum theophylline concentrations, but it recurred despite serum concentrations of 10 to 20 μg/mL, the range considered to be effective and safe for the treatment of asthma. Theophylline should be used with caution for wheezing in infants under age 3 months until its efficacy is proved or disproved and the range of effective serum concentrations and the pharmacokinetics are defined in nontoxic infants delivered at term.

This investigation was supported by the Children's Hospital of Winnipeg Research Foundation Inc.

Numerous nurses and physicians helped us, especially Robert D. Walker, MD, and Shashikant S. Seshia, MD, who cared for the infants. Evelyn Frith and Stuart Fedak, BSc (Pharm) provided technical assistance.

Dr E. Simons is a Queen Elizabeth II Scientist Award recipient.

Malformation Complex

Spondylohypoplasia, Arthrogryposis, and Popliteal Pterygium

Susan Beckwitt Turkel, MD; Allen L. Iseri, MD; Atsuko O. Fujimoto, PhD, MD

• Two unrelated children were born with severe congenital malformations: a girl now seven years old and a boy who died in the newborn period. Both had severe cervical hyperextension, severe flexion deformities of the limbs, and bilateral popliteal pterygia. Postmortem examination of the second case showed small, well-formed thoracic vertebrae with mild epidural fibrosis and hemorrhage. These birth defects are rare and usually occur separately. We postulate that they are related in these two cases; that the arthrogryposis and popliteal pterygia were probably the result of the spondylohypoplasia and associated changes; and that together, these related defects may constitute a new malformation complex.

(*Am J Dis Child* 134:42-45, 1980)

Spondylohypoplasia, arthrogryposis, and popliteal pterygium are rare entities that usually occur as isolated events. In 1973, Fujimoto et al[1] briefly reported an unusual case of multiple skeletal anomalies including severe cervical and thoracic spondylohypoplasia, arthrogryposis, and popliteal pterygium. A second infant, virtually identical to the first, was born at Los Angeles County-University of Southern California (LAC-USC) Medical Center. Although the first child has survived to 7 years of age, the second child died in the newborn period. The recurrence of this same constellation of birth defects suggests a common pathogenesis. These associated defects may constitute a new malformation complex.

REPORT OF CASES

CASE 1.–A female infant was born at term to a 21-year-old healthy gravida 2, para 2 mother of Mexican-American descent. After a breech extraction delivery, the infant was transferred to LAC-USC Medical Center because of multiple congenital anomalies. At birth, the patient weighed 2,381 g. She had notable shortening of the trunk and neck and a protuberant abdomen (Fig 1). The head was hyperextended and seemed to sit directly on the shoulders. The head circumference was 33.5 cm, and the chest circumference was 32 cm. She had severe lordosis and mild scoliosis. The lower limbs had 90° flexion contractures at the knees with bilateral popliteal pterygia extending from the midthigh to calf. Both feet showed mild varus deformities. The upper limbs had flexion contractures of 30° at the elbows, flexion of the wrists, and minimal movement at the metacarpophalangeal and proximal interphalangeal joints. There were hemangiomata on the forehead, upper eyelids, nose tip, and upper lip. The right ear was posteriorly rotated and low set, and there was a cleft of the soft palate and bifid uvula.

Roentgenograms of the cervical, thoracic, and lumbosacral spine indicated posterior fusion of C2-T1, T5-T12, and L3-S2 vertebral bodies (Fig 2). The lower ribs were posteriorly crowded. There seemed to be excess thick bone along the spinous processes of the lumbar vertebral bodies and widening of the vertebral canal in this region. Except for long fingers, the bones of the limbs, skull, and hips appeared normal. Chromosomal analysis of peripheral blood showed a normal 46,XX karyotype by trypsin-Giemsa banding.

The mother used a foam contraceptive during the first trimester. She took a mixture of aspirin, phenacetin, caffeine, and pseudoephedrine hydrochloride (Emprazil) during the first month; a mixture of dicyclomine hydrochloride, doxylamine succinate, and pyridoxine hydrochloride (Bendectin) for nausea during the second month; and subcutaneous injections of epinephrine and parenteral and oral diphenhydramine hydrochloride during the third month for minor allergic reactions. She was exposed to rubella during the fifth month; however, the rubella hemagglutination inhibition titer was 1:160 at the time of exposure and three weeks later. She denied fever but reported chills on several

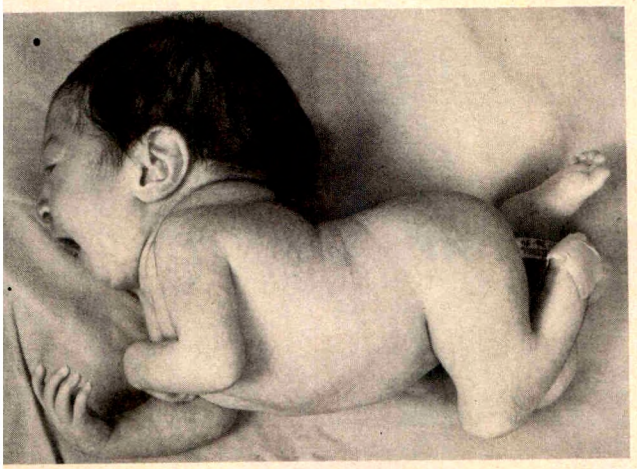

Fig 1.—Lateral view of newborn (case 1). Cervical hyperextension, severe lordosis, and flexion contractures of extremities are illustrated.

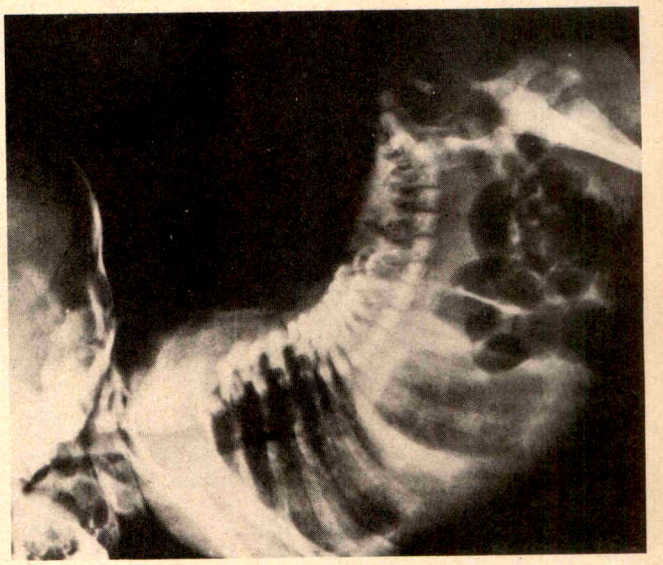

Fig 2.—Case 1. Vertebral and rib abnormalities.

occasions during the first half of pregnancy.

The father was a healthy 37-year-old Mexican-American. The union was nonconsanguineous, with one previous, healthy daughter. A maternal aunt married a paternal uncle and had five normal children. A paternal cousin had a foot abnormality of unknown type that required a brace, the only known malformation in this large kindred.

At 1 month of age, the patient was transferred to a rehabilitation hospital. At age 6 months, bilateral femoral osteotomies were performed to decrease the flexion deformities of the knees. The patient is now 7 years old, and despite intensive attempts at physical therapy, her mobility and function are severely limited. Speech is impaired because the cleft palate has not yet been repaired. Although it is difficult to evaluate her mentation and development, she socializes well and does not seem to be retarded.

Case 2.—A 2,960-g infant was born at 41 weeks' gestation. The mother was admitted to LAC-USC Medical Center in active labor with the fetus in a double footling breech presentation, and the infant was delivered by an emergency cesarean section. The Apgar scores were 1 at one minute and 2 at five minutes. Multiple skeletal anomalies were noted at birth. The baby was severely contorted with a short neck and thorax and hyperextended head (Fig 3). Small, reddish hemangiomata were present on the nose, on the upper lids, and over the eyes. The head circumference was 37.5 cm and the chest circumference was 34.5 cm. Elbows, wrists, fingers, and knees were contracted, and bilateral popliteal pterygia extended from midthigh to calf. He had long, tapering fingers held in ulnar deviation and vertical palmar creases. There was a moderate bilateral varus deformity of the feet. The palate was high arched and intact. The infant was cyanotic, and despite oxygen therapy, he became bradycardic and died at 9 hours of age in respiratory failure.

This infant was the firstborn to 21-year-old, nonconsanguineous parents. The mother had high fevers in the third or fourth month of pregnancy for which she was treated with acetaminophen. Otherwise, the pregnancy was unremarkable. Vitamins and iron were the only other medications taken. The family history was unremarkable.

Radiologic examination showed multiple abnormalities of the ribs and vertebrae, and hemivertebrae were suggested (Fig 4). Chromosomal analysis of peripheral blood lymphocytes indicated a 46,XY normal male karyotype by trypsin-Giemsa banding.

At autopsy, the multiple skeletal malformations were confirmed, but no visceral malformations were found. The lungs were atelectatic and firm, and microscopically showed congestion. The bony abnormalities of the vertebral column were striking. The cervical spine was extremely shortened so that the head sat on the shoulders in extreme dorsiflexion.

The thoracic and lumbar vertebral column was removed intact, then fixed and decalcified before sectioning. This segment measured 10 cm in overall length, and was bent at a 45° angle 4 cm from the cervical end. The portion of spinal column cephalad to the bend consisted of small, flattened vertebrae and thin, intervertebral disks. The most proximal vertebral bodies measured 2 to 3 mm in height and those closest to the bend were 3 to 4 mm in height. In the caudal portion of the vertebral column, which measured 6 cm in length beyond the bend, the vertebral bodies were of more normal size and shape and measured 7 to 8 mm in height (Fig 5).

The spinal cord within the canal was approximately 2 cm shorter than the length of the vertebral column. In the upper segment proximal to the bend, the nerve roots were obscured by dense, honeycombed, hemorrhagic fibrous tissue that was continuous with and adherent to the dura, arachnoid, and periosteum. Below the bend, the dura and meninges were unremarkable; and the nerve roots exited at the usual angle, two vertebral levels below their origin.

Microscopic examination of transverse sections through the grossly abnormal thoracic segment of the spinal cord confirmed fibrosis and hemorrhage. Acute hemorrhage was found in the dense connective tissue between dura and bone as well as surrounding the nerve roots through the intervertebral foramina. The nerves appeared intact and the dorsal root ganglia were also unremarkable. There were scattered glioblasts in the region of the anterior horn neurons that gave this area a slightly hypercellular appearance. The vertebrae were unremarkable, with a normal pattern of endochondral ossification and normal marrow.

The brain was grossly normal. Microscopic examination of sections of cerebellum, cerebrum, thalamus, medulla, and pons showed diffuse mild gliosis of cerebral white matter and mild superimposed edema. Sections of the popliteal pterygia

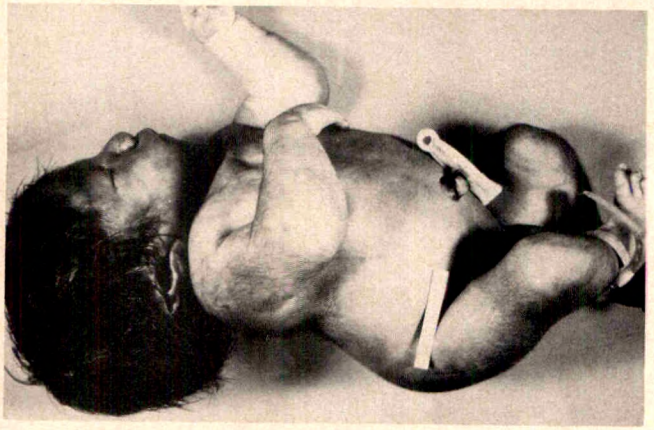

Fig 3.—Lateral view at autopsy (case 2). Hyperextended neck, lordosis, and flexion contractures of extremities are shown.

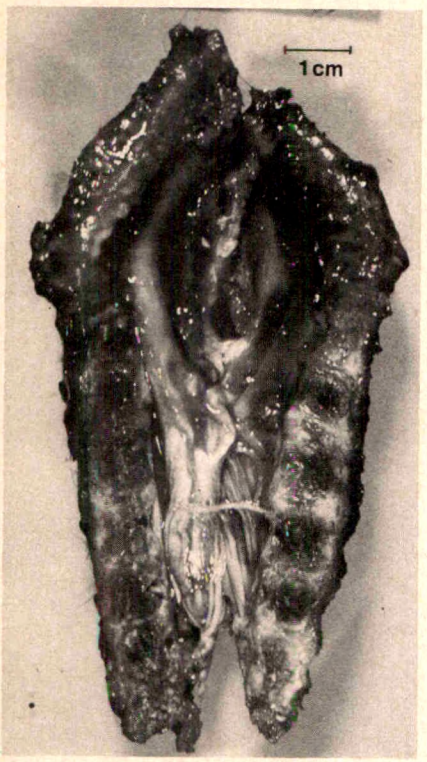

Fig 5.—Thoracic and lumbar vertebral column. Removed at autopsy and longitudinally sectioned, it illustrates hemorrhagic fibrous tissue, small thoracic vertebrae, and normal-appearing lumbar vertebrae.

consisted of nerves, vessels, and connective tissue. The remainder of the autopsy was unremarkable.

COMMENT

To explain the possible pathogenesis of the associated defects found in these two patients, the normal pattern of morphogenesis of affected parts must be understood. The early development of the human vertebral column has been extensively studied by Sensenig.[2] The definitive vertebrae of the spinal column arise from sclerotomal cells that are derived from the ventromedial and ventral aspect of the somites. A secondary sclerotome composed of the caudal half of one segment and the cranial half of the next primary sclerotome is established by the end of the fourth week of intrauterine life. The vertebrae and ribs are in turn derived from this secondary sclerotome, and the rudiments of the ribs and vertebral bodies, arches, and processes are laid down by the end of the fifth week. Chondrification begins by the sixth week, and ossification of the cartilage ensues by the end of the second month. By the end of the first trimester, the definitive shapes of both vertebrae and ribs are accomplished and ossification is well underway.

The upper limb buds begin to take shape by the end of the first month and are essentially formed by the end of the second month. The lower limbs begin about one week later and finish slightly after the arms and hands. Nonetheless, formation of the limbs is essentially complete, and their musculature and innervation well established by the end of the first trimester.[3]

By early in the second trimester when the vertebrae, ribs, and limbs are formed, an insult could impede their further growth but would not result in their malformation. In case 2, the vertebrae were found to be well formed but very small at autopsy. It is likely that the vertebral and rib abnormalities seen by roentgenographic examination of the first child represent similar anatomic alterations found at autopsy in the second case. In these two cases, the vertebral damage may be the primary event, and the rib and limb abnormalities consequent to the abnormal vertebral growth.

Although it is not possible to accurately date the time the vertebrae were damaged, their small size suggests that an injury occurred sometime early in the second trimester. Why the injury occurred only to the cervical and thoracic segments is unknown. A selective infectious or circulatory etiology is possible. It is tempting to relate the documented febrile illness of one mother early in the second trimester and the history of chills occurring sometime in the first part of pregnancy in the other mother to the pathogenesis of the malformations found in these two cases. Another remote possibility is a genetically determined mechanism, such as a new dominant mutation or an autosomal recessive disorder. How-

ever, there is no available evidence to support this hypothesis and it seems less likely.

In most cases of arthrogryposis studied, some defect of the neuromuscular system sufficient to have caused paralysis has been found.[4] In some, only microscopic evidence of decreased anterior horn cells or cerebral abnormalities could be documented. In others, grossly apparent deformities such as meningomyelocele were present. With spinal cord damage, muscle sections usually show the typical histologic pattern of denervation atrophy. But even a milder derangement of neurologic function without histologic change could account for decreased movement in utero and for arthrogryposis. This functional damage to the spinal cord's long corticospinal tracts and spinal nerves could be caused by either torsion or compromised blood supply, both of which could result from severe cervical hyperextension and thoracic deformation.

Although it is difficult to find a specific cause for the arthrogryposis in these two cases, of the various possibilities, this type of functional damage is probably the likeliest. The CNS gliosis found was mild and probably does not represent the primary insult that gave rise to the skeletal abnormalities. The acute hemorrhage found in the spinal canal was probably the result of a perinatal event, and the fibrosis in this area was most likely part of the prior injury; but, again, these changes are probably not sufficient to result in arthrogryposis. Histologic evidence of substantial cord injury was not documented and, accordingly, denervation atrophy or other skeletal muscle changes were also not found.

A popliteal pterygium represents contraction of the neurovascular bundle found at the back of the knee. It may occur as an isolated event or in association with other abnormalities. In these two cases, it probably resulted secondary to the contractures of both knees as part of the arthrogryposis multiplex congenita complex.

According to current terminology, a "malformation" is considered to be a structural abnormality of morphogenesis.[5] Sometimes, it is possible to postulate relationships between multiple malformations involving different structures, and the term "malformation complex" is used to describe such related defects. In these two cases, we postulate such a relationship between the multiple skeletal malformations. We assume the severe spondylohypoplasia probably occurred as the initial defect, and it may be the result of differentially abnormal growth of the previously well-formed cervical and thoracic vertebrae. This led in turn to the changes in the ribs and also, probably owing to functional neurologic derangement, to the arthrogryposis and popliteal pterygia.

In conclusion, we postulate that the spondylohypoplasia, arthrogryposis, and popliteal pterygia are related malformations, and together these changes constitute a new malformation complex.

Dextrose Tolerance in Atrophic Infants

Clinical studies were carried out on four normal infants aged 5 to 15 months, and seven atrophic infants aged 3½ to 13 months whose weights are all well below the third percentile for their ages. Dextrose solutions of "approximately 10, 15, and 20 percent" were given by a continuous infusion pump injected intravenously over at least 30 minutes. The urine was tested for sugar with Haines' solution and was tested before the infusions and again toward or after the end of the infusion. Infused sugar was calculated as grams per kilogram per hour.

In all the normal infants glycosuria was seen at 1.0 gm/kg/hr. In none of the atrophic infants was the tolerance below 1.4 or 1.5 gm/kg/hr. In three atrophic infants glycosuria appeared first at 1.8 gm/kg/hr. Thus glucose appeared to be better tolerated in the sick than in the well infant.

The investigators suggest that "such infants might derive some benefit from intravenous glucose infusions."—P. M. Mattill; K. M. Mayer; L. W. Sauer, The Otho S. A. Sprague Memorial Institute Laboratory, Children's Memorial Hospital, Chicago (19:42, January 1920).

Changes in Zinc Metabolism During the Course of the Nephrotic Syndrome

Ekkehard W. Reimold, MD

• **The plasma zinc concentration and quantitative urinary zinc excretion were studied in 105 pediatric patients with the nephrotic syndrome or nephritis-nephrosis. The plasma level was decreased to a mean value of 51.7 μg/dL in patients with the nephrotic syndrome (controls, 85 μg/dL). The rate of urinary zinc excretion was not different from that of the controls, with the exception of patients whose disease was in the polyuric phase of beginning remission where it was fivefold higher and those who had achieved a long-lasting remission of the disease. Since about two thirds of the plasma zinc is bound to albumin, an unchanged zinc-albumin ratio would reflect an equal zinc and albumin loss. The ratio, however, was increased twofold and thus does not adequately explain the hypozincemia. The low hair level of 86 μg/g may suggest a more profoundly disturbed zinc metabolism than originally thought.**

(*Am J Dis Child* 134:46-50, 1980)

Our interest in studying the plasma concentration and excretory rate of zinc in patients with nephrotic syndrome was stimulated by two observations. In 1942, McCance and Widdowson[1] described two patients with albuminuria that was accompanied by a substantially increased zinc excretory rate. In contrast, Fairhall and Hoyt[2] had found earlier an essentially unchanged rate of zinc excretion in nephritis or nephrosis. In 1972, when studying the aminonucleoside nephrosis of rats, Freeman et al[3] observed an increase in the rate of zinc excretion almost parallel to the increase in the rate of protein excretion. At the same time, the plasma zinc levels decreased below normal. The second observation refers to studies of Flynn et al[4] who reported a precipitous decrease in serum zinc concentration during corticosteroid treatment and who suspected a relation to the adrenocorticotropic hormone production or corticosteroid secretion.

We decided, therefore, to study changes in the metabolism of zinc in patients with the nephrotic syndrome, a disease that by definition is accompanied by substantial proteinuria. In addition, most pediatric patients with the nephrotic syndrome receive prolonged corticosteroid treatment. Our results show that the plasma zinc level is decreased in patients with the nephrotic syndrome as long as proteinuria is present. The rate of urinary zinc excretion, however, is not increased and shows little change during the course of the nephrotic syndrome.

SUBJECTS AND METHODS

A total of 105 pediatric patients who fulfilled the criteria for the nephrotic syndrome (anasarca, proteinuria, hypoalbuminuria, hypercholesterolemia), or glomerulonephritis and nephrotic syndrome (proteinuria, persistent hematuria, transient or constant mild hypertension) were included in this study. They were separated into two groups, 81 patients with idiopathic nephrotic syndrome and 24 patients with a combination of nephritis-nephrosis. Studies were also performed in seven patients with glomerulonephritis, but because of the small number, the data were not included in the statistical evaluation. Selected results are given in this report. These patients were compared with a group of 33 healthy children of corresponding age who were recruited from healthy siblings of our patients. In each instance, including the healthy controls, a 24-hour urine collection and blood and hair samples were obtained. The majority of our patients and all control subjects were not hospitalized at the time of this study. The mean age was 7 years (range, 1 to 16 years). The diagnosis of nephritis-nephrosis represents cases of early membranoproliferative glomerulonephritis, focal glomerulosclerosis, and membranous and diffuse proliferative glomerulonephritis. The renal function as measured by creatinine clearance or serum creatinine level was not substantially decreased in these cases.

The patients also were grouped according to their disease activity, as determined by presence or absence of proteinuria, and

From the Department of Pediatrics, University of Texas Southwestern Medical School, Dallas.

Reprint requests to Department of Pediatrics, 2600 Sixth St SW, Canton, OH 44710 (Dr Reimold).

vere separated into different treatment groups. In the majority of cases, the disease progressed from an initial state where proteinuria was present but treatment had not been started (group 1) to the point where proteinuria was still evident but treatment with prednisone (2 to 3 mg/kg/24 hr) was also given (groups 2 and 3). In group 2, patients are listed who received daily prednisone administration, whereas patients who were changed to a Monday-Wednesday-Friday treatment schedule were entered into group 3.

Remission of the disease was characterized by a return of the urinary protein excretory rate to less than 150 mg/24 hr (groups 4 to 6). Again, the results were categorized into three groups, patients who received daily prednisone therapy (group 4), who received intermittent prednisone administration (group 5), or who did not require any treatment (group 6). Patients with the additional diagnosis of glomerulonephritis were assigned to the same groups although corticosteroid treatment was used much less frequently. A dietary history was not obtained in our patients or the controls.

The quantitative excretion or the concentration of zinc in urine, plasma, and hair was studied in our patients. At the same time, the rate of excretion of creatinine and protein and the serum concentration of total protein, albumin, α_2-globulin, and creatinine were measured. Hair samples were obtained from the occipital area, with the hair cut close to the scalp and the proximal 2 cm used for analysis (20 to 60 mg of hair). Hair samples were washed with nonionic detergent and deionized water and, prior to chemical determination, were ashed in concentrated nitric acid. The amount of zinc was determined by atomic absorption spectrophotometry according to a modification of the method of Meret and Henkin,[5,6] total protein by the use of biuret reagent according to a modification of the method as published by Mattenheimer,[7] and serum protein fractions by protein electrophoresis using cellulose acetate electrophoresis. The mean and SD were calculated for the data of each group, and the level of significance was calculated for each set of data.

RESULTS

Zinc and Protein Levels in Plasma

All patients with the nephrotic syndrome or a combination of nephritis and nephrosis had decreased serum total protein and albumin levels but increased α_2-globulin concentrations (Table 1). They maintained low serum protein and albumin levels as long as proteinuria was present, even during corticosteroid therapy. During active disease, the mean serum albumin level in patients with nephrotic syndrome was 1.7 g/dL (control, 4.0 g/dL). At the same time, the α_2-globulin concentration was increased to 1.42 g/dL (control, 0.6 g/dL).

The plasma zinc concentration was also low in all children with active nephrotic syndrome or nephritis-nephrosis (mean, 50 and 52 μg/dL, respectively) (Fig 1), whereas all patients with glomerulonephritis maintained a normal level (79 ± 14.5 μg/dL). With improvement in the disease condition, an increase in plasma zinc concentration was observed, particularly in children in disease remission, although the level remained slightly low (mean, 69 μg/dL) in most cases.

protein fractions, the ratio between zinc and total protein, albumin, or α_2-globulin was calculated (Table 2). The latter two are the two major plasma protein fractions that bind and transport zinc. Table 2 gives the ratio of zinc to total protein as slightly but not significantly lower in patients with proteinuria than in controls. On the other hand, the zinc-albumin ratio increased during proteinuria more than twofold compared with the controls and decreased only after excessive proteinuria had ceased. We also observed a threefold decrease in the zinc-α_2-globulin ratio in almost all groups. In children in remission and no longer receiving therapy, however, the value was not significantly different from that of controls (Table 2).

Urinary Excretion of Zinc and Protein

The mean rate of protein excretion in patients with the nephrotic syndrome was 2.3 g/24 hr (range, 0.6 to 5.7 g/24 hr) during active disease. Overall, there was no significant difference between children with "minimal change" nephrotic syndrome and those who had an underlying glomerulonephritis although there was considerable individual variability. In patients with nephrotic syndrome, the proteinuria remained essentially unchanged as long as the disease was active and was independent of prednisone treatment (Table 3). Patients whose disease was in remission had, by definition, a normal protein excretion.

The quantitative zinc excretion in children with nephrotic syndrome or nephritis-nephrosis was significantly ($P < .01$) elevated in only two groups (Fig 2). Children who underwent massive diuresis during early remission excreted zinc in quantities up to 2,500 μg/24 hr (mean, 1,895 μg/24 hr), an amount that is several times that of the corresponding controls. Also, patients whose disease was in complete remission and who were no longer receiving steroid therapy excreted about twice as much zinc as the controls.

Important information may be obained from the ratio of zinc to protein n the urine (Fig 3). This ratio was low n all children with proteinuria).9 ± 0.8 μg/mg) and increased bout eightfold to tenfold to 8.3 ± 5.8 g/mg in patients with normal proein excretion.

Hair Zinc Content

The mean hair zinc level was 86 g/g, with values ranging as low as 49 g/g for our patients with nephrotic yndrome or nephritis-nephrosis as ompared with a level of 125 to 150 g/g for control children of the same ge (Fig 4). Similarly, low levels were ound for children who had stopped eceiving prednisone treatment after hey had achieved remission of the lisease for nine to 12 months. Patients with glomerulonephritis, owever, had normal hair zinc concenrations.

COMMENT

The plasma zinc level was decreased n our patients with the nephrotic yndrome as long as proteinuria was present. The same observation was eported during the course of the minonucleoside nephrosis of rats.[3] An increase occurred in remission, but he level remained low even in patients who were free of disease for an extended time period. To find an explanation for the low plasma zinc concentration, we have studied the relation between zinc and important plasma protein fractions. Essentially all plasma zinc is protein-bound, about 30% firmly to an α_2-macroglobulin,[8-10] the remainder loosely to either albumin (about 60%) or other low molecular weight complexes (about 10%). The exact ratio of these plasma zinc fractions is still in dispute.[11-13] We found an increase in the serum zinc-albumin ratio in the presence of proteinuria that indicates a proportionately larger albumin loss. The concentration of the second important transport protein, serum α_2-globulin, was increased compared with that of zinc. The zinc-globulin ratio was threefold lower in the nephrotic patients than in the controls, and it was slightly decreased even in children whose disease was in complete

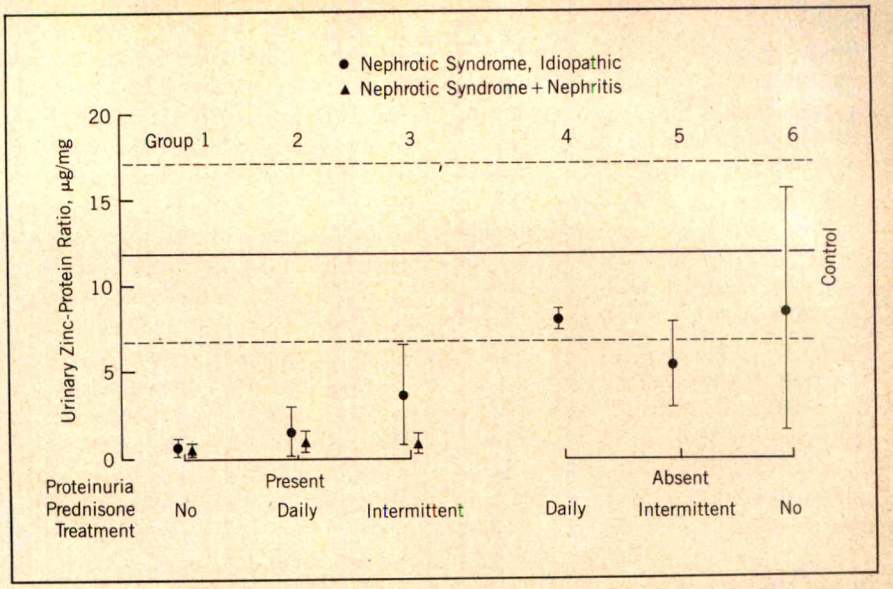

Fig 3.—Zinc-protein ratio in urine is significantly lower for patients with nephrotic syndrome than for control patients as long as proteinuria is present. As soon as proteinuria has ceased, value is not significantly different from that of controls.

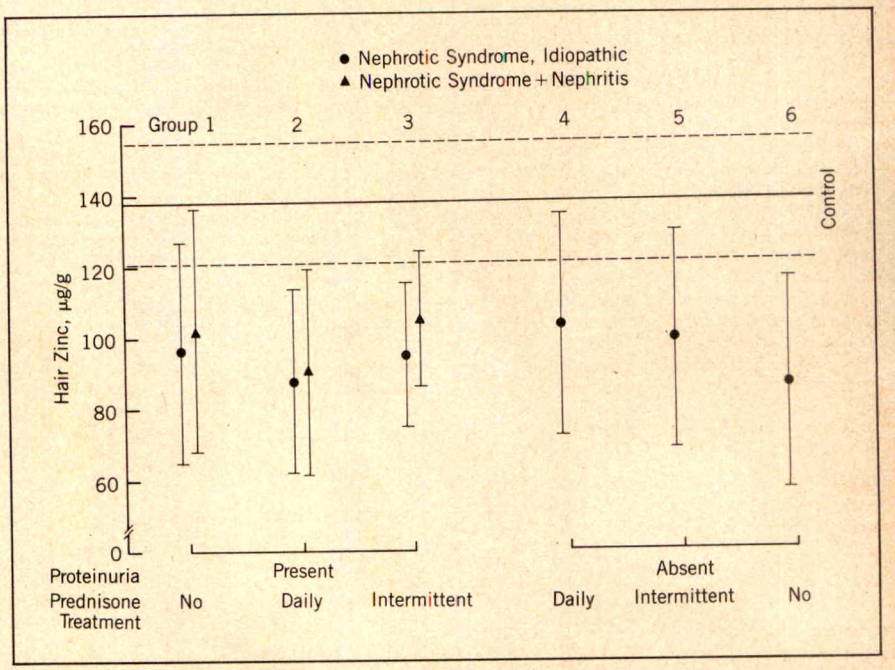

Fig 4.—Concentration of zinc in hair of patients with nephrotic syndrome or nephritis-nephrosis is decreased throughout entire observation period as compared with control patients. Difference is statistically significant ($P < .05$).

remission. These two findings speak against the assumption that the hypozincemia is correlated to changes in these important zinc transport proteins despite the fact the zinc-total protein ratio remained unchanged.

Also, we found that prednisone treatment did not lower the plasma zinc concentration. We could not document a difference between children treated with prednisone and those who did not receive prednisone treatment as long as their disease was in a comparable stage. The observation of Flynn et al[4] to the contrary may be explained by the fact that our patients received this hormone for a long period of time, allowing for a gradual correction of acute changes.

In our study, the low plasma zinc

level could not be explained by an increased rate of urinary zinc excretion. In fact, the urinary zinc excretory rate showed little change during the course of the nephrotic syndrome. This is in contrast to the brief report of McCance and Widdowson[1] and to the results of the aminonucleoside nephrosis study in rats.[3] Only Fairhall and Hoyt[2] reported an unchanged rate of zinc excretion in patients with nephritis or nephrosis. Two points, however, require mentioning: (1) In seven patients whose disease was in the polyuric phase of beginning disease remission, a threefold to fourfold increase in the zinc excretory rate was observed, which probably lasted only for a short period because the rate of zinc excretion was found to be low in all children whose disease was in complete remission. (2) The urinary zinc excretory rate was higher in children who had achieved a full, long-lasting remission and who were not receiving steroid treatment than in control patients. Dietary factors are an unlikely explanation for the increased rate of zinc excretion. Although some pathologic conditions like starvation or excessive zinc administration are known to increase the rate of urinary zinc excretion in a healthy subject,[14] the renal zinc excretion plays only an insubstantial role in maintaining the zinc balance. At least 80% of the ingested zinc is eliminated through the gastrointestinal tract, and less than 10% is excreted in the urine.[15] Moderate dietary changes of zinc intake are not reflected in an increased rate of urinary zinc excretion. All these factors suggest that additional, presently unknown factors exert an influence on the zinc balance in patients with the nephrotic syndrome.

Finally, the low zinc concentration in hair of most patients with the nephrotic syndrome or nephritis-nephrosis may suggest a more profoundly disturbed zinc balance than was thought. This question could not be answered with the information available from this study and is presently under investigation.

Deborah J. Besch and Paula Thompson provided secretarial aid, and they have carried out and completed this research.

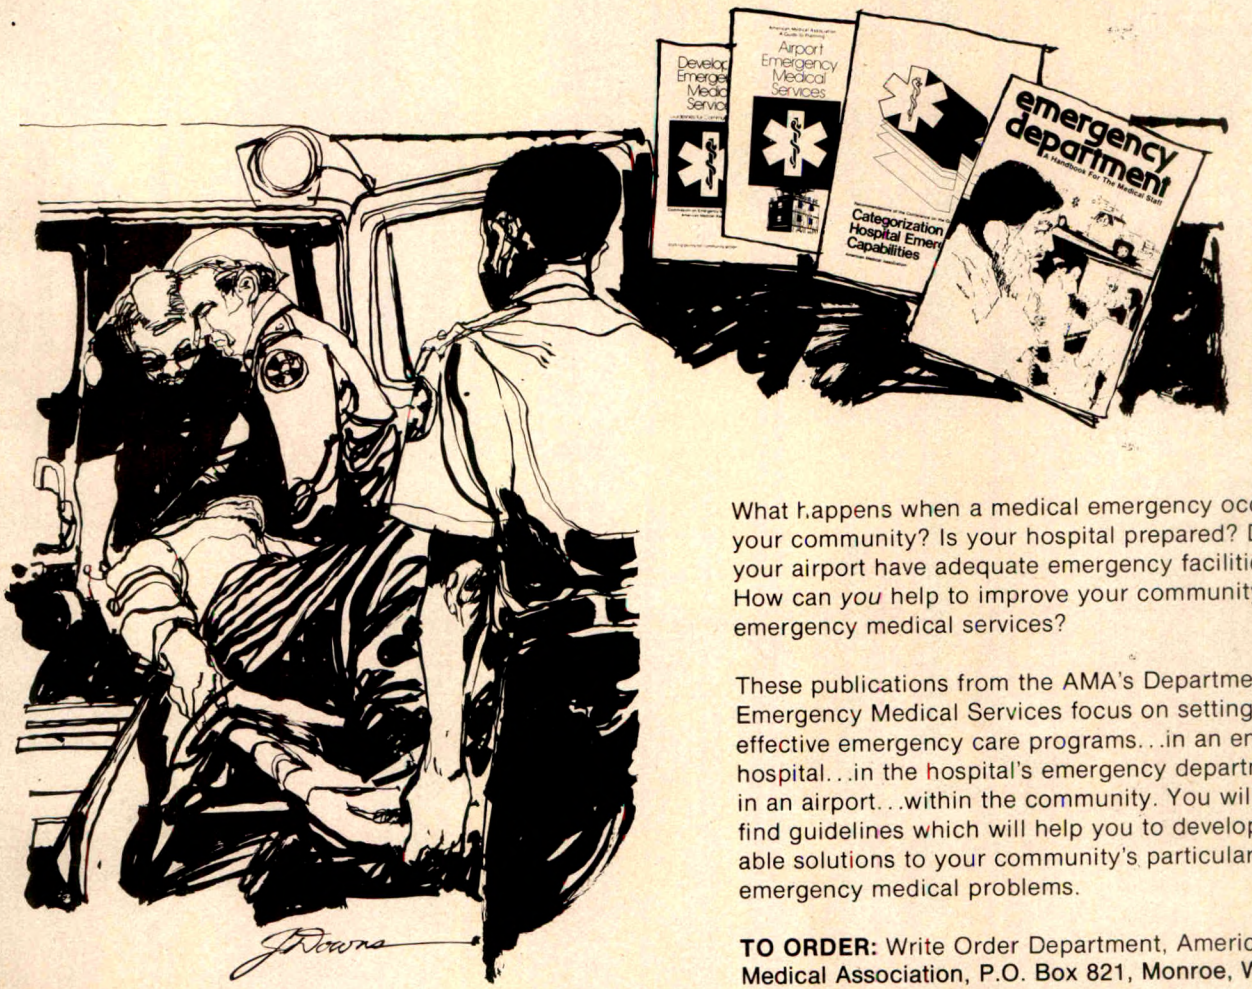
How Can You Help to Improve Your Community's Emergency Preparedness?

Consult these AMA Emergency Medical Care publications.



What happens when a medical emergency occurs in your community? Is your hospital prepared? Does your airport have adequate emergency facilities? How can *you* help to improve your community's emergency medical services?

These publications from the AMA's Department of Emergency Medical Services focus on setting up effective emergency care programs...in an entire hospital...in the hospital's emergency department...in an airport...within the community. You will find guidelines which will help you to develop workable solutions to your community's particular emergency medical problems.

TO ORDER: Write Order Department, American Medical Association, P.O. Box 821, Monroe, WI 53566. Please specify title, OP number, and include payment with your order. Allow 4-5 weeks for delivery.

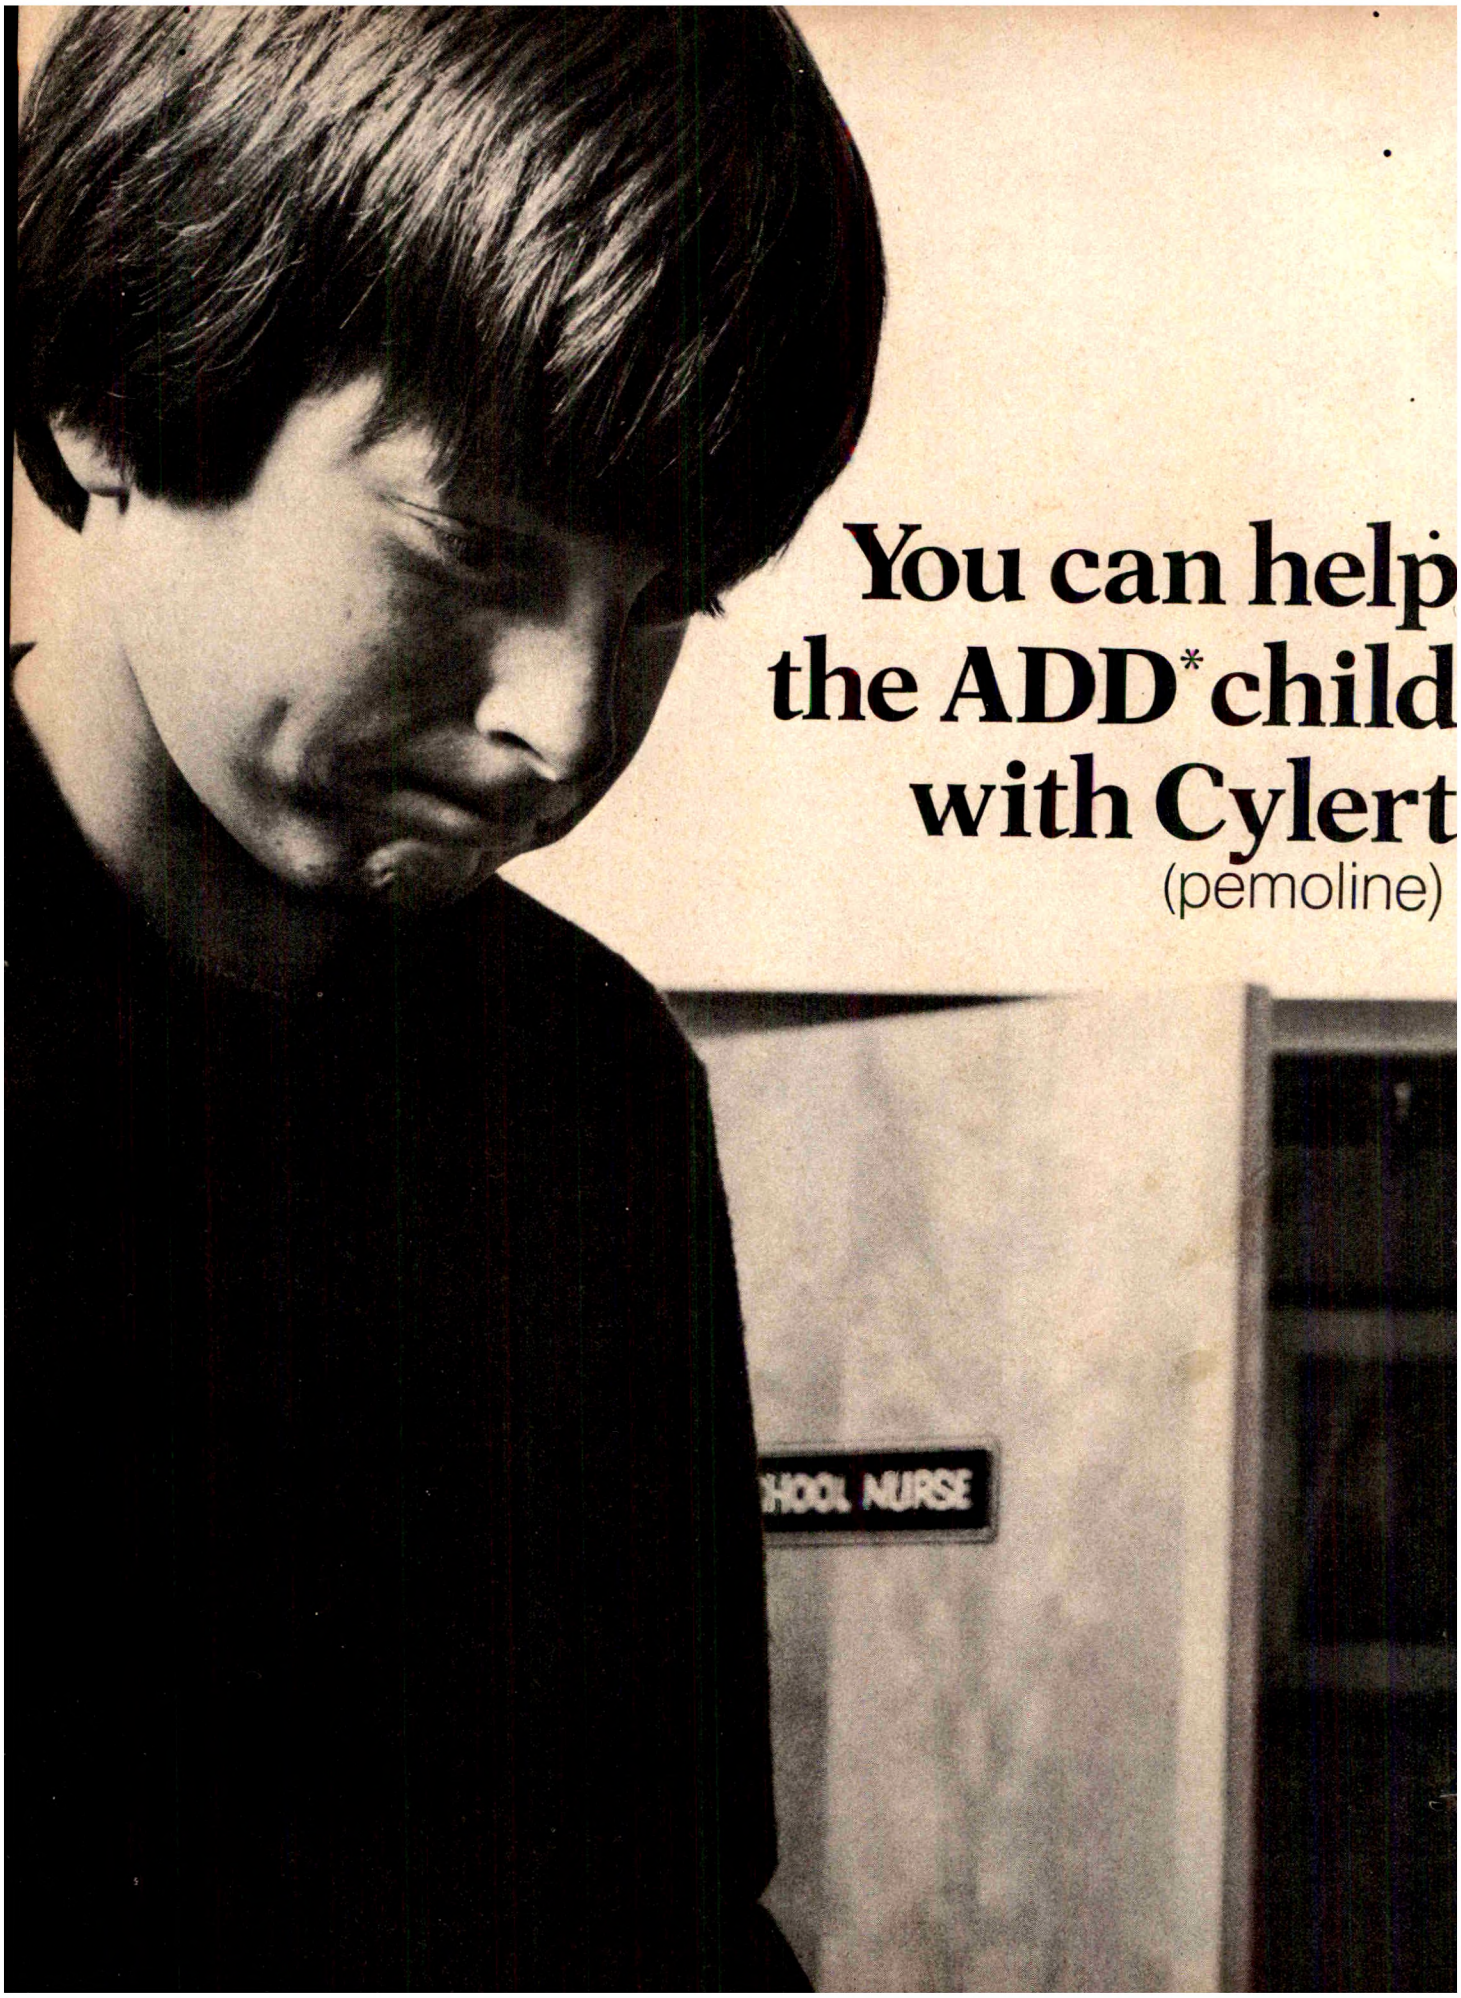
PUBLICATIONS

Categorization of Hospital Emergency Capabilities (OP-387) $.55
The Commission on Emergency Medical Services of the AMA sets forth recommended guidelines for four categories of hospital emergency services for adults, children and infants, including newborns, that could function in community systems of emergency medical capabilities.

Emergency Department--Handbook for Medical Staff (OP-131 $2.00
How can the emergency department be an effective area for medical education? What are its legal implications? These and other related topics are explored in this manual which helps to establish workable solutions to problems in the emergency department. (Available November 1976)

Developing Emergency Medical Services--Guidelines for Community Councils (OP-386) $.75
In an effort to upgrade emergency medical care and reduce the number of needless accidental deaths, the AMA's Commission on Emergency Medical Services provides guidelines which deal with the establishment of community councils on emergency medical services and the various stages of developing good emergency medical services.

Airport Emergency Medical Services (OP-085) $.85
This new guide outlines the major functions of an emergency medical services plan, plus the key elements in providing such services, which should be common to all airports. Includes illustrations and appendices.



You can help the ADD* child with Cylert
(pemoline)

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® (pemoline) **C IV**

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

Day-long behavior therapy without dosing problems at school

Cylert® (pemoline) CIV

Just once a day. At home.

Brief Summary of Prescribing Information

INDICATIONS—CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS—CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS—CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS—Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS—Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT; a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities, nystagmus and nystagmoid eye movements, and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE—Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION—CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

HOW SUPPLIED—CYLERT (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (white) in bottles of 100 (**NDC** 0074-6025-13)
37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6057-13)
75 mg. tablets (tan-colored) in bottles of 100 (**NDC** 0074-6073-13)

CYLERT Chewable is supplied as monogrammed, grooved tablets in one dosage strength:

37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6088-13)

Breakthrough in cystic fibrosis screening!

The Webster Sweat Collection System from Wescor.

Featuring a unique heated sweat collection cup that virtually eliminates condensate error.

Serious errors affecting the correct diagnosis of cystic fibrosis are likely to occur during the sweat collection procedure. One such error, known as the condensate error, can now be virtually eliminated by using the new Wescor heated cup shown on this child's arm. Preheated to 40°C, the cup prevents condensation of water on its interior surface during the sweat collection period. There is little or no patient discomfort.

With condensate error under control, an important step is taken toward eliminating false positives and negatives. The Webster System, which combines iontophoresis and sweat collection, allows analysis by osmometry, conductance, or by sodium, chloride and potassium microassay. Dr. Webster[1] reports that osmometry offers greater precision and sensitivity of readout than conductivity. Laboratories with vapor pressure osmometers will find this analysis attractive economically. The Webster system costs just $995 complete.

To learn more about how the Webster system provides you with a truly representative sample of a patient's sweat, call, write, or circle the reader service number.

How Supplied

CYCLAPEN® (cyclacillin) tablets:
250 mg scored tablets
500 mg scored tablets

Indications

Cyclapen® (cyclacillin) has less in vitro activity than other drugs in the ampicillin class of antibiotics and its use should be confined to the indications listed below.

Cyclapen® is indicated for the treatment of the following infections:

RESPIRATORY TRACT
Tonsillitis and pharyngitis caused by Group A beta-hemolytic streptococci
Bronchitis and pneumonia caused by *S. pneumoniae* (formerly *D. pneumoniae*)
Otitis Media caused by *S. pneumoniae* (formerly *D. pneumoniae*) and *H. influenzae*
Acute exacerbation of chronic bronchitis caused by *H. influenzae**
*Though clinical improvement has been shown, bacteriologic cures cannot be expected in all patients with chronic respiratory disease due to *H. influenzae*.

SKIN AND SKIN STRUCTURES (integumentary) infections caused by Group A beta-hemolytic streptococci and staphylococci, non-penicillinase producers.

URINARY TRACT INFECTIONS caused by *E. coli* and *P. mirabilis*. (This drug should not be used in any infections caused by *E. coli* and *P. mirabilis* other than urinary tract infections.)

NOTE: Cultures and susceptibility tests should be performed initially and during treatment to monitor the effectiveness of therapy and the susceptibility of bacteria. Therapy may be instituted prior to the results of sensitivity testing.

Contraindications

The use of this drug is contraindicated in individuals with a history of an allergic reaction to penicillins.

Warnings

CYCLACILLIN SHOULD ONLY BE PRESCRIBED FOR THE INDICATIONS LISTED IN THIS INSERT.

CYCLACILLIN HAS LESS *IN VITRO* ACTIVITY THAN OTHER DRUGS OF THE AMPICILLIN CLASS ANTIBIOTICS. HOWEVER, CLINICAL TRIALS HAVE DEMONSTRATED THAT IT IS EFFICACIOUS FOR THE RECOMMENDED INDICATIONS.

SERIOUS AND OCCASIONAL FATAL HYPERSENSITIVITY (ANAPHYLACTOID) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING PENICILLIN.

ALTHOUGH ANAPHYLAXIS IS MORE FREQUENT FOLLOWING PARENTERAL ADMINISTRATION, IT HAS OCCURRED IN PATIENTS ON ORAL PENICILLINS. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS. THERE ARE REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY REACTIONS WHO EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH A CEPHALOSPORIN. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE ABOUT PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, THE DRUG SHOULD BE DISCONTINUED AND APPROPRIATE THERAPY SHOULD BE INITIATED. SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE, OXYGEN, INTRAVENOUS STEROIDS, AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

Precautions

Prolonged use of antibiotics may promote the overgrowth of nonsusceptible organisms. If superinfection occurs during therapy, appropriate measures should be taken.

PREGNANCY: Pregnancy Category B. Reproduction studies have been performed in mice and rats at doses up to ten times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cyclacillin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

NURSING MOTHERS: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when cyclacillin is administered to a nursing woman.

Adverse Reactions

The oral administration of cyclacillin is generally well tolerated.

As with other penicillins, untoward reactions of the sensitivity phenomena are likely to occur, particularly in individuals who have previously demonstrated

CYCLAPEN® (cyclacillin) for oral suspension
125 mg per 5 ml:
100 ml and 200 ml bottles
250 mg per 5 ml:
100 ml and 200 ml bottles

hypersensitivity to penicillins or in those with a history of allergy, asthm fever, or urticaria.

The following adverse reactions have been reported with the use of cycl diarrhea (in approximately 1 out of 20 patients treated), nausea and vo (in approximately 1 in 50), and skin rash (in approxrmately 1 in 60). Is instances of headache, dizziness, abdominal pain, vaginitis, and urticari been reported. (See WARNINGS)

Other less frequent adverse reactions which may occur and that have reported during therapy with other penicillins are: anemia, thrombocyto thrombocytopenic purpura, leukopenia, neutropenia and eosinophilia. reactions are usually reversible on discontinuation of therapy.

As with other semisynthetic penicillins, SGOT elevations have been rep

Dosage and Administration

INFECTION*	ADULTS	CHILDREN
		Dosage should not in a dose higher tha for adults.
Respiratory Tract		
Tonsillitis & Pharyngitis**	250 mg q.i.d. in equally spaced doses	body weight <20 k lbs) 125 mg q.i.d equally spaced dose body weight >20 k lbs) 250 mg q.i.d equally spaced dose
Bronchitis and Pneumonia		
Mild or Moderate Infections	250 mg q.i.d. in equally spaced doses	50 mg/kg/day q.i. equally spaced dose
Chronic Infections	500 mg q.i.d. in equally spaced doses	100 mg/kg/day q.i. equally spaced dose
Otitis Media	250 mg to 500 mg q.i.d. in equally spaced doses depending on severity	50 to 100 mg/kg/d equally spaced dose pending on severity
Skin & Skin Structures	250 mg to 500 mg q.i.d. in equally spaced doses depending on severity	50 to 100 mg/kg/d equally spaced dose pending on severity
Urinary Tract	500 mg q.i.d. in equally spaced doses	100 mg/kg/day in eq spaced doses.

*As with antibiotic therapy generally, treatment should be continued minimum of 48 to 72 hours after the patient becomes asymptomatic or evidence of bacterial eradication has been obtained.

**In infections caused by Group A beta-hemolytic streptococci, a minimu 10 days of treatment is recommended to guard against the risk of rheur fever or glomerulonephritis.

In the treatment of chronic urinary tract infection, frequent bacteriologic clinical appraisal is necessary during therapy and may be required for se months afterwards.

Persistent infection may require treatment for several weeks.

Cyclacillin is not indicated in children under 2 months of age.

Patients with Renal Failure

Based on a dosage of 500 mg q.i.d., the following adjustment in do interval is recommended:

Patients with a creatinine clearance of >50 ml/min need no age interval adjustment.

Patients with a creatinine clearance of 30-50 ml/min should receive doses every 12 hours.

Patients with a creatinine clearance of between 15-30 ml/min sh receive full doses every 18 hours.

Patients with a creatinine clearance of between 10-15 ml/min sh receive full doses every 24 hours.

In patients with a creatinine clearance of < 10 ml/min serum creatinine values of ≥ 10 mg %, serum cyclacillin levels are rec mended to determine both subsequent dosage and frequency.

Wyeth Laboratories

Partial Resolution of Bone Lesions

A Child With Severe Combined Immunodeficiency Disease and Adenosine Deaminase Deficiency After Enzyme-Replacement Therapy

Barry S. Yulish, MD; Robert C. Stern, MD; Stephen H. Polmar, PhD, MD

• A child with severe combined immunodeficiency disease and adenosine deaminase deficiency, with characteristic bone dysplasia, was treated with transfusions of frozen irradiated RBCs as a means of enzyme replacement. This therapy resulted in restoration of immunologic competence and partial resolution of the bone lesions. Although the natural history of these lesions without therapy is not known, enzyme-replacement therapy may have played a role in the resolution of this patient's bone lesions.

(*Am J Dis Child* 134:61-63, 1980)

Adenosine deaminase (ADA) deficiency is associated with an autosomal recessive form of severe combined immunodeficiency disease (SCID).[1] In addition to immunodeficiency, a characteristic bone dysplasia has been observed in many children with this condition.[2,3] Bone dysplasias similar to those of ADA-deficient patients with SCID have also been reported for various syndromes associated with immunologic incompetence.[4-8] However, the ADA status of these patients was not reported. Roentgenographic features of the bone dysplasia in patients with ADA deficiency include broad, flared, and cupped anterior ends of ribs, and pelvic abnormalities that include flat, irregular acetabular roofs, decreased vertical height of the innominate bones, and narrow sacrosciatic notches.[2] Mild platyspondylia and increased height of intervertebral disk spaces as well as cupping of the posterior rib ends are less prominent findings.[2] Children with SCID have an absence of both cell-mediated and humoral immunity and, if untreated, usually die of infection before age 2 years. Bone marrow transplantations from histoidentical donors have resulted in immunologic reconstitution in some patients.[9] We have treated a child with SCID associated with ADA deficiency with repeated transfusions of frozen irradiated RBCs as a source of ADA.[10] This form of enzyme-

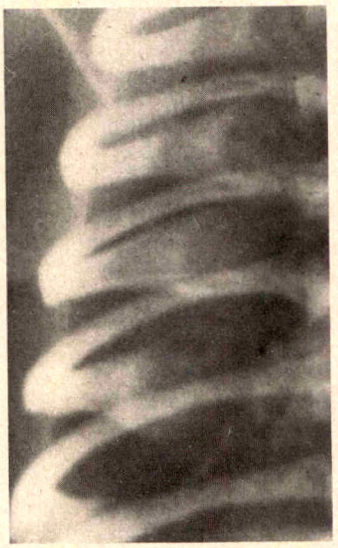

Fig 1.—Ribs shortly after birth. Note cupping of anterior rib ends.

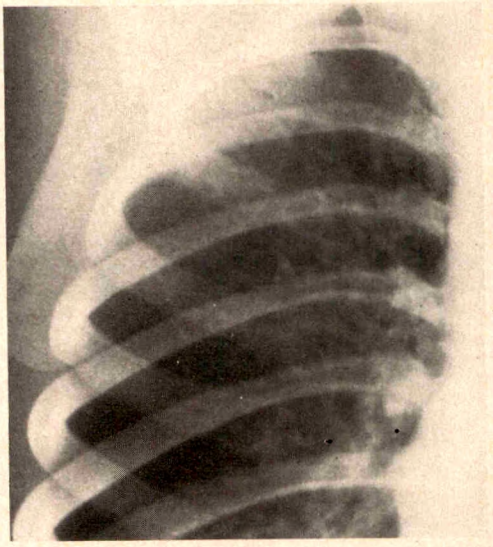

Fig 2.—Ribs at age 2 years. No cupping of rib ends is present.

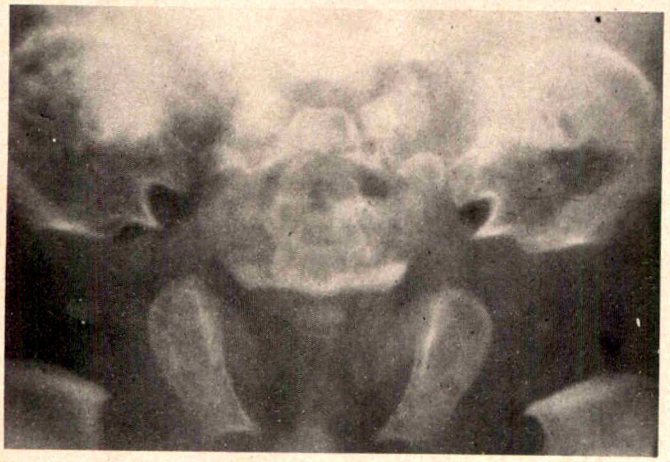

Fig 3.—Pelvis at age 3 months. Note short vertical height of iliac bones, flat acetabular roofs, short sacrosciatic notches, and wide ischia.

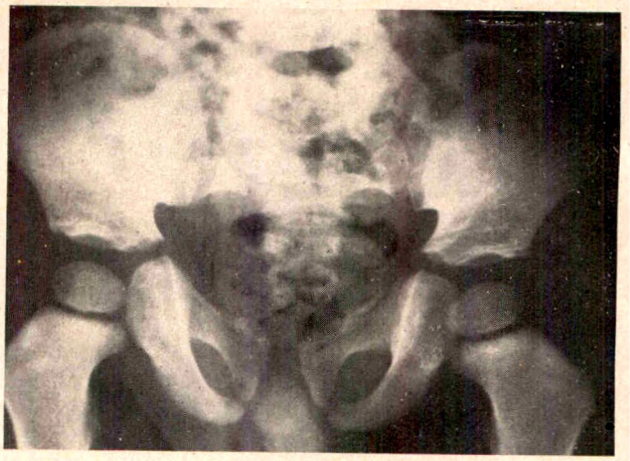

Fig 4.—Pelvis at age 2 years. Acetabular roofs are not as flat, sacrosciatic notches are not as narrow, but ischia are still widened.

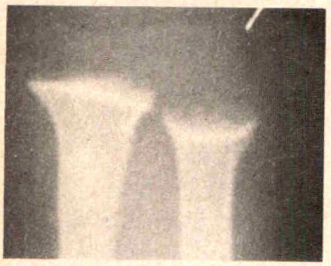

Fig 5.—Wrist at age 3 months. Metaphyses are broad, cupped, and flared.

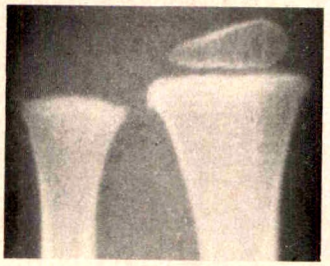

Fig 6.—Wrist at age 2 years. Note normal appearance of metaphyses.

Fig 7.—Normal bony pelvis of infant for comparison.

replacement therapy restored both humoral and cell-mediated immunity. Roentgenograms of the chest on the day of birth and of the chest and bones up to age 7 months demonstrated characteristic bone lesions as well as flaring and cupping of some long-bone metaphyses. Treatment was begun at 7 months of age and, after 17 months of therapy with intermittent transfusions of RBCs, roentgenograms made at age 2 years demonstrate great resolution of bone lesions.

REPORT OF A CASE

Adenosine deaminase deficiency was diagnosed prenatally by measurement of ADA activity in cultures of amniotic cells after amniocentesis.[11] The patient was transferred to Rainbow Babies and Childrens Hospital, Cleveland, at 1 day of age and placed in protective isolation, which was maintained until one week prior to discharge from the hospital at 12 months of age. The diagnosis of SCID was confirmed by studies of in vitro lymphocyte responses and immunologic evaluation. In vitro studies demonstrated that exogenous ADA restored normal lymphocyte-proliferative responses to mitogens.[12] These studies suggested that in vivo administration of ADA might improve the immunologic function of the patient. Blood transfusion is usually contraindicated in SCID because of the risk of graft vs host disease. However, frozen irradiated RBCs, which are free of viable lymphocytes, were found to be a safe source of encapsulated human ADA.[10] At age 7 months, the child received the first of several transfusions of frozen irradiated RBCs. This therapy resulted in the restoration of both humoral and cell-mediated immunity.[10] He was subsequently discharged home and has been readmitted for transfusion of frozen irradiated RBCs at four- to six-week intervals. He has remained free of clinically apparent infection throughout his course of treatment, except for three urinary tract infections and a perianal abscess prior to the beginning of therapy. His height and weight have followed the tenth-percentile line.

RESULTS

Rib abnormalities were present on a roentgenogram made at birth (Fig 1) but not on one made at age 2 years (Fig 2), after 17 months of ADA-replacement therapy. Pelvic abnormalities present at age 3 months (Fig 3), have regressed at age 2 years (Fig 4), with increased size of the sacrosciatic notches and more slope to the acetabular roofs. Some pelvic abnormalities persist, however, including broad ischia.

Wrist roentgenograms made at age 3 months (Fig 5) show broad, cupped, and flared metaphyses, but those made at age 2 years (Fig 6) show no abnormalities.

Figure 7 shows a normal bony pelvis of an infant for comparison.

COMMENT

The bone dysplasia demonstrated in our patient shortly after birth has many features characteristic of ADA deficiency-SCID.[2] Similar bone dysplasias have been reported in other immunologically deficient patients,[4-8] but the ADA status of these patients is unknown. The rib abnormalities alone are not specific, but may also be seen in patients with SCID and normal RBC ADA.[2]

The natural history of the bone lesion is unknown, although histologic study of the costochondral junctions and vertebrae by Cederbaum et al[13] showed absence of the zone of proliferative cells, lack of organized cartilage-cell columns, uninterrupted formation of calcified cartilage, and lack of trabecular formation. It is possible that the dysplasia could regress with advancing age even in the absence of any treatment, but few patients whose conditions were untreated have survived beyond 2 years of age. Bone lesions have recently been reported to improve after bone marrow transplantation; however, this procedure results in metabolic changes similar to those observed in patients treated by RBC enzyme-replacement therapy.[14] Thus, bone marrow transplantation interferes with the natural history of the metabolic disturbance in ADA deficiency and these patients cannot serve as controls for the patients whose conditions were treated with RBC transfusions.

Patients with ADA deficiency have been found to have elevated levels of adenosine triphosphate (ATP), deoxy-ATP, and cyclic adenosine-3′, 5′-monophosphate (cAMP) in their lymphocytes.[10,15,16] We have hypothesized that the mechanism by which transfusion restores immunocompetence is that the RBC ADA catabolizes adenosine or deoxyadenosine that diffuses out of the lymphocytes and into the RBCs.[10] This reduces the lymphocyte adenosine (or deoxyadenosine) levels and eliminates the accumulation of excess ATP, deoxy-ATP, and cAMP. It is tempting to speculate that a similar metabolic defect is operative in osteoblasts or chondroblasts (ie, that intracellular levels of adenosine and cAMP are excessive and that the RBC ADA catabolizes adenosine that diffuses out of the osteoblasts or chondroblasts). Further observation on the course of the bone defect in patients with untreated ADA deficiency as well as in those whose conditions are treated with intermittent RBC transfusions or bone marrow transplants will help elucidate the pathophysiology of the bone defect and could provide new insight concerning normal bone growth.

Metabolic Studies in a Child With a Pancreatic Insulinoma

Fredda Ginsberg-Fellner, MD, Elliot J. Rayfield, MD

• **An 8-year-old boy with a convulsive disorder for 3½ years remained seizure free for 20 months while being treated with phenytoin (diphenylhydantoin) sodium, and then he had a relapse. He first demonstrated hypoglycemia when he fasted prior to being placed on a ketogenic diet. An oral glucose tolerance test indicated fasting and postglucose hypoglycemia and substantial hyperinsulinemia. Somatostatin infusion resulted in a modest increase in plasma glucose levels and a decrease in serum insulin concentrations. A discrete pancreatic mass was demonstrated preoperatively by celiac angiography that on surgical extirpation, proved to be a benign intrapancreatic insulinoma. Evaluation for islet cell tumors is of importance in children with seizure disorders unresponsive to anticonvulsant medication. Furthermore, somatostatin may be useful preoperatively in maintaining normal blood glucose concentrations in patients with islet cell adenomas.**

(*Am J Dis Child* 134:64-67, 1980)

Pancreatic islet cell adenomas are uncommon in childhood. Zuppinger[1] summarized 48 cases, whereas Cornblath and Schwartz[2] indicated that 88 cases have been described. All authors agreed that most children had neurologic symptoms, convulsions being the most prominent.[3,4] The use of phenytoin (diphenylhydantoin) sodium in such children has rarely been commented on although this agent is often used as an anticonvulsant and is known to inhibit insulin secretion. Recently, we studied an 8-year-old child who had been treated with phenytoin for 3½ years and who subsequently was found to have a benign pancreatic insulinoma. During the period prior to surgery, maintenance of normal blood glucose levels in our patient was difficult. Therefore, somatostatin, a tetradecapeptide hormone widely distributed in the CNS, gastrointestinal tract, and delta cells of the islets of Langerhans[5-8] and a known inhibitor of insulin, glucagon, and growth hormone secretion,[9-12] was used in an effort to increase the patient's blood glucose concentrations. We report the results of metabolic studies in this patient after fasting, oral dextrose administration, and somatostatin infusion.

REPORT OF A CASE

An 8-year-old boy was admitted to Mount Sinai Medical Center with a three-year history of recurring seizures. At age 4½ years, he first had several nocturnal screaming episodes. An EEG was abnormal, and treatment with phenytoin resulted in complete remission of these symptoms for 20 months. Recurrent episodes of weakness and flaccidity followed by hunger for sugar-laden cereals ensued and were not relieved by increases in the dose of phenytoin. Ten months prior to the present hospitalization, the EEG and results of CSF and neurological examinations were all normal; a fasting plasma glucose level was 70 mg/dL, and a two-hour postprandial value was 78 mg/dL. Eight months later, the EEG, computerized axial tomography, skull roentgenograms, and results of serum magnesium, calcium, toxicology, plasma amino acids, and three fasting blood glucose tests were all normal.

Despite the fact that carbamazepine (Tegretol) and primidone (Mysoline) were added to the anticonvulsant therapy, the seizures increased in frequency, and the patient was readmitted to the hospital for institution of a ketogenic diet. He was an obese, highly irritable child. His height was 118 cm (< third percentile for age); weight, 24.5 kg (50th percentile for age and height); and head circumference, 53 cm. An EEG then showed severe cerebral dysfunction. Serum thyroxine, triiodothyronine, and thyroid-stimulating hormone by radioimmunoassay, urinary vanillylmandelic acid and urinary free cortisol levels were all within normal limits. Bone age was 7 years and 8 months. The patient was begun on a diagnostic fast, and within two hours, he had generalized seizures develop. The plasma glucose level was then 25 mg/dL, the serum insulin level was 96 μU/mL and the glucose-insulin ratio was 0.26 (adult normal, ≥6[13]; normal range for children in our laboratory, 8 to 15). Phenytoin therapy was

then discontinued. One day later, an oral glucose tolerance test was performed; dextrose, 1.75 g/kg, as a 50% solution (43 g) was administered. Ten days later, a somatostatin infusion was started; 330 μg of somatostatin was given during a 40-minute period, followed by 500 μg during the next 30 minutes. This latter test was performed to determine the feasibility of inhibiting exaggerated insulin release preoperatively; when maintenance of normal plasma glucose concentrations can be extremely difficult. Celiac and superior mesenteric angiograms showed a discrete 1- to 2-cm lesion in the midportion of the pancreas. Liver scan was normal.

For the 11 days prior to surgery, plasma glucose levels were maintained between 50 and 80 mg/dL by the use of a 1,600-calorie diet (60% carbohydrate, 15% protein, 25% fat) divided into six to eight meals and of a 10% dextrose solution, intravenously, that provided dextrose at 0.28 g/kg/hr. At surgery, a 1.5-cm well-encapsulated intrapancreatic mass was identified immediately superior to the junction of the superior mesenteric and inferior pancreatic arteries and was then excised. No other masses were found. The pathologic picture was that of a typical insulinoma, with tumor cells, on light microscopic examination, forming both islet and ribbon-like structures. On ultrastructural studies, there were cytoplasmic granules typical of those normally seen in beta cells of the islets of Langerhans. No other cell types were identified. Microscopic sections of the pancreas, not involved by tumor, were completely normal. During surgery, plasma glucose values peaked at 350 mg/dL immediately after removal of the tumor, whereas the serum insulin level decreased from 35 to 16 μU/mL 14 minutes after tumor removal and to 9 μU/mL 46 minutes later. Postoperatively, serum amylase levels peaked at 220 units and the plasma glucose level gradually decreased from 285 mg/dL to 88 mg/dL by the seventh day. Glycosuria was present until the third postoperative day. The patient has remained asymptomatic during the past 24 months, with fasting glucose values ranging from 70 to 84 mg/dL and serum insulin levels ranging from 6 to 10 μU/mL.

MATERIALS AND METHODS

Plasma glucose was measured by the glucose-oxidase method with an automated system of chemical analysis. Serum immunoreactive insulin (IRI), growth hormone,[14] proinsulin,[15] and plasma glucagon,[16] were measured by radioimmunoassay procedures. The glucagon assay was performed using 30K glucagon antiserum purchased from Roger Unger, MD. Informed consent was obtained for all studies from the patients' parents. Permission for use of the somatostatin (Emergency IND No. 12460, Federal Drug Administration, Edwin Ortiz) was obtained. The somatostatin was obtained from Roger Guillemin, MD, PhD, at the Salk Institute, San Diego, in the form of dihydrosomatostatin as synthesized by Jean Rivier. It was dissolved in physiologic sodium chloride solution (0.5 mg/mL) and filtered through a 0.22-μ filter (Millipore) into 2-mL unit dose, pyrogen-free vials, with a concentration of 1 mg/mL. It was then further diluted in physiologic saline solution just prior to use at a final concentration of 20 μg/mL and was administered by an infusion pump.

RESULTS

Glucose Tolerance Test

The results of the glucose tolerance test are depicted in Fig 1. Fasting and postglucose hypoglycemia are noted. The fasting glucose level was 34 mg/dL and a nadir of 20 mg/dL was reached two hours after dextrose ingestion. This was accompanied by notable hyperinsulinemia at all test points, with a peak value of 334 μU/mL at 15 minutes (normal, 50 μU/mL) and a value of 144 μU/mL when blood glucose reached its lowest level at the two-hour point. Fasting hyperinsulinemia (50 μU/mL; normal, 2 to 20 μU/mL) was also present. As shown in Fig 1, the fasting proinsulin level of 9.5% was within the normal range (normal, 5% to 22%); at two hours, however, the value rose to 23.6%.

Somatostatin Infusion

The results of the somatostatin infusion are shown in Fig 2. Plasma glucose levels gradually increased, beginning 20 minutes after the start of the somatostatin infusion. The 38% increase from 47 to 65 mg/dL occurred gradually during the final 50 minutes of the study period; it was greatest between 20 and 30 minutes, at the time the lower somatostatin dosage was being infused. Plasma glucagon levels (75 to 95 pg/mL) were within the normal range in our laboratory (50 to 120 pg/mL; with normal children's values in the higher limit) and did not change substantially during the infusion. Serum growth hormone declined by 50% during the first 20 minutes of the study. This was followed by a paradoxical increase to 7.4 ng/mL 30 minutes after the start of the somatostatin infusion. Thereafter, growth hormone levels declined steadily for the remainder of the study.

COMMENT

Islet cell tumors are rare during childhood, with convulsions and behavioral changes being prominent in both the pediatric and adult age groups. In adults, delay in diagnosis has been reported to be associated with administration of phenytoin. Thus, a 44-year-old man described by Knopp et al[17] had convulsions for 17 years; withdrawal of the anticonvulsant resulted in an increase in insulin levels from 20 to 41 μU/mL. In children, prior administration of phenytoin was only documented in three cases, and there were no comments as to how drug administration affected the patient's clinical course or metabolic evaluation.[18-20] Our patient initially had a therapeutic response to phenytoin for 20 months. However, convulsive episodes recurred, and he experienced fasting hypoglycemia and an exaggerated insulin response to oral dextrose administration. The blunting effect on insulin secretion by phenytoin has been documented in adults with islet cell tumors,[21] normal children and adults,[22,23] laboratory animals,[24] and in vivo islet cell systems.[25] Also note that fasting proinsulin levels were not elevated in our patient, in contrast to the situation usually described in adults.[15] The normal proinsulin levels, too, could be an effect of phenytoin administration.

Similar reduction in beta cell tumor insulin release has recently been reported after the administration of somatostatin. Thus, Scuro et al[26] reported that somatostatin infusions produced slight decreases in basal insulin levels and inhibition of glucose-, glucagon-, and tolbutamide sodium-induced insulin release in two women, one of whom had a documented pancreatic insulinoma. Curnow and co-workers[27] showed that somatostatin suppressed elevated insulin levels in a 54-year-old woman with metastatic pancreatic islet cell carcinoma. Similar suppression was

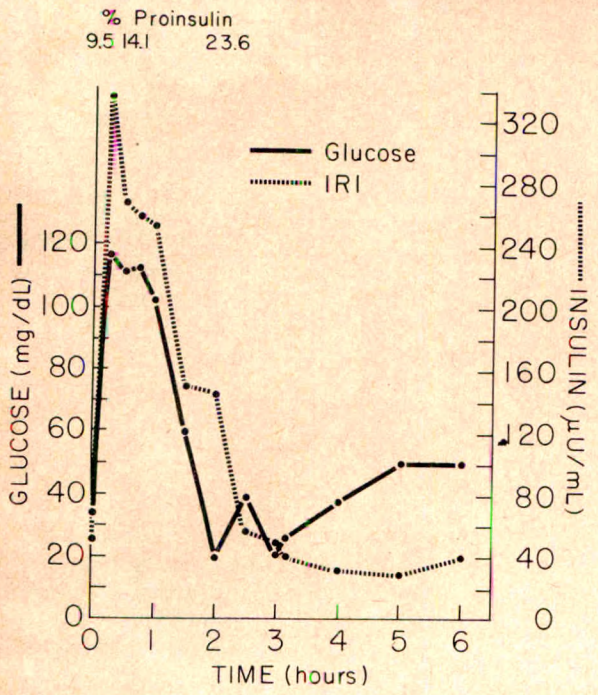

Fig 1.—Oral glucose tolerance test. IRI indicates immunoreactive insulin. Percent proinsulin concentrations (of total IRI) are indicated at 0, one half, and two hours.

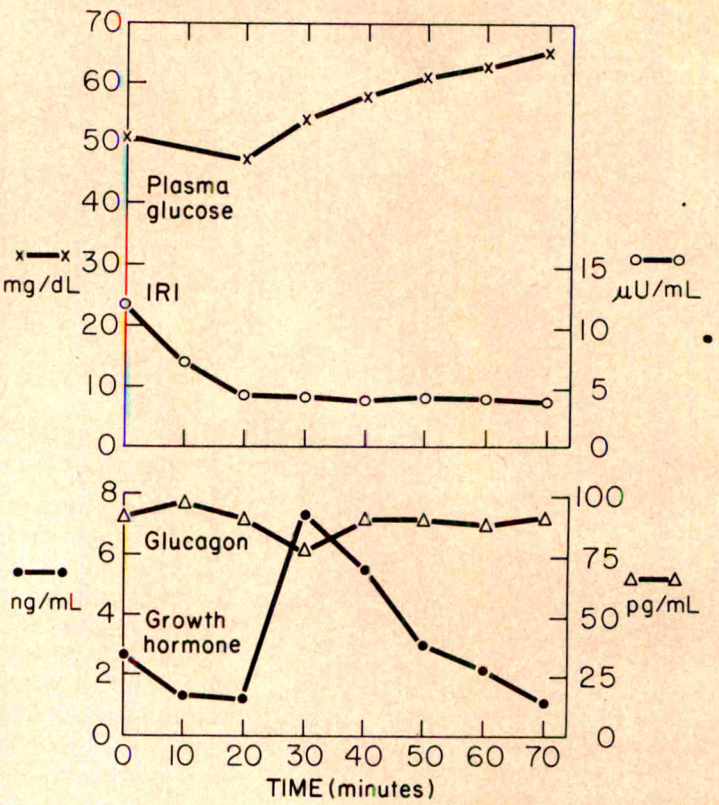

Fig 2.—Somatostatin infusion study. Plasma glucose concentrations and serum immunoreactive insulin (IRI) concentrations are shown in upper panel. Plasma immunoreactive glucagon concentrations and serum growth hormone concentrations are depicted in lower panel.

more recently reported in an infant with nesidioblastosis.[28] In that child, administration of synthetic cyclic somatostatin at a rate of 120 μg/hr (or 20 μg/kg/hr) resulted in a decrease of serum IRI from 6.8 to 2 μU/mL within 20 minutes after the start of the somatostatin infusion. The rise in the blood glucose level, however, did not occur until one hour after the serum insulin level began to fall. In our patient, the somatostatin's suppression of insulin and the increase in the plasma glucose level both commenced at the same time, within ten minutes of the beginning of the starting, lower-dosage (20.2 μg/kg/hr) somatostatin infusion. In addition, the increase in the plasma glucose level continued throughout the time of infusion, whereas the serum insulin level fell to its nadir of 4 μU/mL 20 minutes after the start of the somatostatin administration and did not decrease further despite the 100% increase in the dosage of the somatostatin to 40.8 μg/kg/hr.

Therefore, similar somatostatin dosages (20 μg/kg/hr) in both our patient with an insulinoma and in the infant with nesidioblastosis[28] produced similar patterns of depression of serum IRI concentrations. The lag in resultant increases in plasma glucose concentrations in the child with nesidioblastosis may reflect the different pathologic picture of the two disease entities or may result from the nature of the different types of somatostatin used in the two studies.

Thus, the insulin-producing cells in both our patient and in the infant with nesidioblastosis showed increased sensitivity to somatostatin that was reflected by slowly increasing blood glucose concentrations. Glucagon levels, however, were not suppressed, which is also similar to the results reported in the infant with nesidioblastosis. Although the glucagon levels in our patient were inappropriately low in the presence of hypoglycemia, comparably low fasting glucagon levels have recently been reported in 12 patients with solitary islet cell adenomas.[29] In these latter subjects, whose ages ranged from 15 to 68 years, plasma immunoreactive glucagon concentrations ranged from 42 to 141 pg/mL, with a mean of 96 pg/mL. These data suggest some derangement in the regulation of glucagon secretion by glucose in such patients as well as a decreased sensitivity to somatostatin-induced inhibition of glucagon release.

The paradoxical rise in growth hormone in our patient during somatostatin infusion was also seen in the infant with nesidioblastosis under similar circumstances. In both children, however, growth hormone levels decreased after this paradoxical rise. The reasons for this temporary "escape" in growth hormone suppressibility by somatostatin remain to be elucidated.

It is apparent from our experience and a review of the literature that all children with unremitting seizure disorders should have fasting blood glucose and simultaneous serum insulin determinations performed to identify possible pancreatic islet cell tumors. Furthermore, physicians

should be aware that phenytoin may initially obscure the diagnosis of insulinoma. Thus, stimulation and suppression tests, including oral glucose tolerance, tolbutamide stimulation, and fasts with sequential insulin determinations, may be required after phenytoin therapy has been discontinued. Finally, somatostatin may be useful in reducing insulin secretion in the preoperative period when maintenance of normal blood glucose concentrations may be extremely difficult.

This work was supported in part by research grant AM 18522 and Research Career Development Award KO4-AM00089 (Dr Rayfield) from the National Institutes of Health.

Charles Brill, MD, referred this patient. Erica Sapira provided excellent technical assistance. Arthur Rubenstein, MD, measured the serum proinsulin levels. The Arnel Co, Brooklyn, NY, supplied rabbit anti-guinea pig serum.

Foreign Body in the Airway

A Review of 200 Cases

Shraga Blazer, MD; Yehezkel Naveh, MD; Abraham Friedman, MD

• **Two hundred children aged 6 months to 12 years were admitted to the hospital with a foreign body in the airway. Food materials constituted 93% of all foreign bodies. A positive history of foreign body aspiration was obtained in 88% of the cases. The most common symptoms of laryngotracheal foreign bodies were dyspnea, cough, and stridor, whereas those of bronchial foreign bodies were cough, decreased air entry, wheezing, and dyspnea. Chest fluoroscopy contributed to the diagnosis in 90% of the cases of bronchial foreign bodies, but only 32% of those in the laryngotracheal area. Of the foreign bodies removed, 98½% were done by laryngoscopy, tracheoscopy, and/or bronchoscopy. Complications were involved in 6% of the cases, including one death. History of recurrent intractable pneumonia should make one consider a foreign body in the airway. Removal of one foreign body does not exclude the existence of another. The condition may be fatal; thus immediate removal of the foreign body is mandatory.**

(*Am J Dis Child* 134:68-71, 1980)

The presence of a foreign body in the respiratory tract is a serious and, on occasion, fatal condition.[1,2] Early diagnosis and removal of the inhaled material may save the patient chronic illness, an existence as an invalid, or possibly death. Despite the great progress in the methods of endoscopy and anesthesia, great difficulties and complications are still present owing to limitations of diagnostic procedures. This report highlights the particular clinical and roentgenographic features and problems of laryngotracheal and bronchial obstruction after the inhalation of foreign bodies by 200 infants and children.

From the Department of Pediatrics B, Rambam Medical Center of the Faculty of Medicine of the Technion-Israel Institute of Technology, Haifa, Israel.

Reprint requests to Department of Pediatrics B, Rambam Medical Center, Haifa, Israel (Dr Blazer).

SUBJECTS AND METHODS

In the course of 12 years, from 1966 to 1977 inclusive, 200 cases of airway obstruction owing to foreign bodies were treated in the pediatric departments, Rambam Medical Center, Haifa, Israel. We reviewed the records of those patients, noting the age and sex of each patient and the time lag between the aspiration or onset of symptoms and hospitalization. In 193 infants and children, chest roentgenograms that included inspiratory and expiratory anteroposterior and lateral films were performed, and in 192 children, fluoroscopy was performed, and the correlation between them and the endoscopic results was noted.

This review includes 197 cases in which the presence of foreign bodies in the respiratory tracts was proved by laryngoscopy, tracheoscopy, and/or bronchoscopy, one case by thoracotomy, and two cases by the coughing out of the aspirated foreign body.

RESULTS

Approximately 85% of the patients studied were less than 3 years of age, and the youngest patient was 6 months old (Table 1). The male-female ratio was about 2:1.

Only 54% of the children were referred to the hospital within three days of aspiration or onset of symptoms and signs, whereas 18% of the children were sent to the hospital after more than one month, either because their parents failed to seek medical attention for their child or because the physician did not realize the true cause of the symptoms (Table 2). In most cases (88%), the children were known to have aspirated something. Table 3 gives the incidence of initial symptoms and signs according to the site of lodgment of foreign bodies.

The most common roentgenographic finding in those patients with bronchial foreign bodies was obstructive emphysema. More than one half of the children with laryngotracheal foreign bodies had normal chest roentgenograms (Table 4). The most common fluoroscopic finding in those patients with bronchial foreign bodies was inspiratory shift of mediastinal shadow, and normal fluoroscopic findings were the most common in those patients with laryngotracheal foreign bodies (Table 5).

Of all the foreign bodies, 76% were lodged in the main bronchi, and 17% were lodged in the larynx or trachea (Table 6). Most foreign bodies were organic (93%), and almost half of all foreign bodies were peanuts (Table 7). All children less than 1 year of age aspirated organic foreign bodies.

The most common complication of foreign body aspiration was pneumonia (22%). Atelectasis was seen in 10% of the cases, bronchiectasis in 1%, and pneumothorax in 0.5%.

Pneumonia	28 (17.5)	6 (18.2)
Normal	25 (15.6)	20 (60.6)
Atelectasis	20 (12.5)	.....
Radiopaque foreign body	6 (3.8)	2 (6)
Pneumothorax	1 (0.6)	.....
Bronchiectasis	1 (0.6)	.....

*More than one of these findings are present in some cases.

Table 5.—Chest Fluoroscopic Findings

	Site (N = 192)	
	Bronchial (N = 161)	Laryngotracheal (N = 31)
Findings	No. (%)	No. (%)
Inspiratory shift of mediastinal shadow	145 (90.1)	4 (12.9)
Inspiratory widening of mediastinal shadow	7 (4.3)	10 (32.3)
Normal	7 (4.3)	15 (48.4)
Inconclusive	2 (1.3)	2 (6.4)

Bronchoscopy was performed within 24 hours of admission in 79% of those with bronchial foreign bodies, and laryngotracheoscopy in 51% of the cases with foreign bodies in the larynx or trachea. Of the foreign bodies removed, 98% were done by laryngoscopy, tracheoscopy, and/or bronchoscopy. In 15%, a second or a third bronchoscopy was needed, either because the foreign body was not found in a previous procedure (9%) or because an incomplete removal was made (6%). Two children coughed out the foreign body and one patient needed a thoracotomy.

One patient died during the bronchoscopic procedure owing to cardiac arrest. Tracheostomy was performed in five patients because of laryngeal edema. Mediastinal and subcutaneous emphysema were seen in three patients, pneumothorax in two patients, and convulsion in one patient.

An improvement in the fluoroscopic appearance of the chest within six days after endoscopy was seen in 75% of all children in whom abnormalities were seen before the endoscopic procedure (Table 8).

Table 6.—Lodgment Site of Inhaled Foreign Bodies

Site (N = 200)	No. (%)

> 20	4 (2.6)

COMMENT

In accordance with the findings of Aytac et al,[3] the greatest danger period of foreign body aspiration is below the age of three years. Maximal

frequency was noted between 1 to 2 years of age, this observation being reported also by others.[4-6] At this age, anything is likely to go into the child's mouth, and without the molar teeth he cannot chew certain edibles finely enough to swallow them.[7] Others[3,7,8] have reported a male-female ratio of 2:1. Pyman[8] hypothesized that this ratio can be explained by the more adventurous and inquisitive nature of males.

The fact that 18% of all children arrived at the hospital more than a month after aspiration is disquieting, bearing in mind that a positive history of aspiration was obtained in 73% of those children. This finding necessitates more watchfulness and accurate history-taking in every child suffering from respiratory symptoms and/or signs.

Manifestations of Aspiration of a Foreign Body

Almost every respiratory symptom or sign might be due to the aspiration of a foreign body. Those manifestations are determined by a number of factors, the most important of which follow.

The Effect of the Foreign Body on the Airflow.—This effect may be in the form of a check, stop, ball, or bypass valve.[9] Accordingly, the effect of the foreign body on the airflow may be altered with every change in its site of lodgment, and this depends on the foreign body's size and shape.[8-10]

Nature of the Foreign Body.—A foreign body of vegetable origin causes the greatest difficulties especially if retained for a considerable time.[9-11] Because of the small group of inorganic foreign bodies in our study, any difference between the patients who aspirated organic and those who aspirated inorganic foreign bodies cannot be statistically significant. All foreign bodies inhaled by infants less than 1 year of age were food materials. This surprising fact may be due to the alertness of the parents to choose adequate infant toys on the one hand and the neglect of proper food preparation (peeling, grinding, mashing, etc) on the other hand. Hence, we are obliged to bring to the parents' notice the importance of proper preparation of infant food.

Latent Period After Foreign Body's Aspiration.—Surface sensory receptors of the respiratory tract become adapted to prolonged pressure caused by a foreign body once lodged in its site. Coughing will not recur until other sensory receptors are stimulated either by movement of the foreign body or by secretions. Consequently, the latent period may vary from hours to months or years.[8]

Although it is impossible to separate the clinical manifestations of the foreign body according to all the aforesaid factors, and such a classification will be useless to the physician, the differences between the clinical manifestations of the bronchial and the laryngotracheal foreign bodies justify such a division. The most common clinical manifestations of the laryngotracheal foreign bodies seen in more than 62% of our patients were dyspnea, cough, and stridor. Those manifestations of the bronchial foreign bodies seen in more than 58% of our patients were cough, decreased air entry, dyspnea, and wheezing (Table 3).

Despite the radiolucency of the majority of the foreign bodies,[3,6,7] their existence is often suggested owing to the secondary effects they produce on the lungs. The radiological investigation must consist of anteroposterior and lateral films in both phases of respiration.[3,7-9,12] Our results demonstrate the limitations of plain chest roentgenograms in the diagnosis of aspirated foreign bodies (1) since 60% of the children with foreign bodies in their larynges or tracheas had normal chest roentgenograms; (2) since 16% of the children with bronchial foreign bodies had normal chest roentgenograms; and (3) since findings of pneumonia per se in chest roentgenograms may impede making the correct diagnoses. Infiltration can be due to primary pneumonia or infected atelectasis after aspiration of a foreign body. This fact is well known and some authors[13] have suggested the use of fluoroscopy as an additional diagnostic procedure. Abnormal behavior of mediastinal shadow during the respiration is sought by means of fluoroscopy.

Types of Mediastinal Changes

Six types of mediastinal changes in shape and size during inspiration have been described by Lederer et al.[14] The two most important are included here.

Inspiratory Widening of Mediastinal Shadow.—This widening is a diagnostic sign of laryngeal, tracheal, or both main bronchi obstruction. Inspiration becomes forced, and intrathoracic pressure becomes much lower than the atmospheric pressure. This pressure gradient causes increased venous return into the heart, and the heart's shadow demonstrates inspiratory widening on fluoroscopy. This widening can also be caused physiologically during a forced inspiration voluntarily closing the glottis, and therefore, the widening of the heart's shadow may be seen if a cry or a forced shout precedes inspiration.

Inspiratory Shift of Mediastinal Shadow.—This shift indicates a unilateral bronchial obstruction. In lesser degrees of impairment to air inflow, this sign is visible only at the beginning of inspiration ("initial shift").

Diagnostic and Therapeutic Considerations

A comparison of the data of Tables 4 and 5 shows that fluoroscopy increases significantly the percentage of accurate diagnoses in cases of bronchial foreign bodies (90% vs 62%). Whereas the discrepancy between the fluoroscopic and bronchoscopic findings was 8.6% in the bronchial foreign bodies, that between the fluoroscopic and bronchoscopic findings in the laryngotracheal foreign bodies amounted to 61% of the cases (normal in 48% and mediastinal shift in 13%). Since inspiratory widening of the mediastinal shadow can be the result of upper airway obstruction, it can be concluded that fluoroscopic examination can be sometimes misleading in the diagnosis of laryngotracheal foreign bodies. These misleading fluoroscopic results impeded early intervention (within 24 hours of admission) in 15 children with laryngotracheal foreign bodies.

Whereas the diagnostic problems of bronchial foreign bodies can be solved by using the lung scanning tech-

nique,[15,16] the diagnostic difficulties of the laryngotracheal foreign bodies, which are not rare in childhood as some have suggested,[17] are not solved yet. Some special roentgenographic techniques failed in detecting foreign bodies in this area. Doust et al,[18] who studied the xeroradiographic detection of laryngotracheal foreign bodies in killed dogs, found that the detection of foreign bodies depends on their size and nature. Moreover, the high radiation dosage necessary in xeroradiography further limits its use in children. Rosenfield et al[19] found that xeroradiography contributed to the diagnosis of upper airway obstruction in only one out of nine cases. Tomography of the airway is impossible in infants and small children who cannot suspend respiration for the time of exposure.[19] Meanwhile, one must attach great importance to the history and clinical manifestations in those cases with normal findings from radiologic examination.

Endoscopy was performed, when possible, as an elective procedure, in the forenoon when the team was at its best and hospital ancillary services were available. The endoscopic procedure needs teamwork and necessitates good communication between the endoscopist and anesthesiologist. Careful preparation of the instruments and specific instructions to the endoscopic team will reduce morbidity and mortality. Management of endoscopy took into account Holinger's advice:[20] "If two hours are spent in such preparation, the safe endoscopic removal of the foreign body may take only two minutes. But if only two minutes are taken for preparation, the endoscopist may find himself attempting makeshift ineffective procedures for the next frustrating two hours."

Every patient arrived at the operating room with an intravenous infusion in place that provided fluids and a convenient route for administering drugs. Atropine sulfate was used for premedication to block the parasympathetic activities caused by the use of the bronchoscope and to reduce the patient's reflexes.

The anesthetic treatment commenced with the introduction of halothane, nitrous oxide, and oxygen. The patient then received intravenously an adequate dose of succinylcholine chloride, and after relaxation, the bronchoscope was inserted, through which the anesthetic gases continued to be administered. When the foreign body was removed, the patient received hydrocortisone acetate intravenously to avoid edema of the larynx, administration of anesthetic gases was stopped, and 100% oxygen was provided until normal respiration was restored.

Patients with bronchial foreign bodies of prolonged sojourn accompanied by infection received a brief but intensive course of antibiotics. In some cases, 8 mg/kg/day of hydrocortisone acetate were added to the therapeutic regimen to reduce endobronchial edema around the foreign body and to ease subsequent extraction. The antibiotic course was continued after endoscopy. Patients with foreign bodies of short sojourn and uncomplicated removal did not have postoperative therapy. Our low rate of complications (6%) after bronchoscopy is in accordance with that of Daniilidis et al[5] (5%), and much lower than those of Teig and Grønas[4] (12%), and Harboyan and Nassif[6] (30%).

The fact that in 15% of all patients a second or even a third bronchoscopy was performed indicates that a normal bronchoscopic result does not exclude the presence of a foreign body in the airway and that the finding of one foreign body does not exclude the presence of another. Therefore, an additional bronchoscopy must be performed if the clinical symptoms continue after normal or abnormal findings of a bronchoscopic procedure. Occasionally, clinical signs will improve after incomplete removal of one or more foreign bodies. Since 75% of the children had fluoroscopic improvement within six days after endoscopy (Table 8), a follow-up chest fluoroscopy should be routinely performed after one week, even if there are no clinical signs.

Finally, the physician should bear in mind that a foreign body in the respiratory tract can result in a variety of respiratory symptoms and signs and that awareness and alertness to the existence of a foreign body in the airway can save much trouble, morbidity, and mortality in infants and children.

Abraham Benderly, MD, and Isaac Eliachar, MD, of the Rambam Medical Center, Haifa, Israel, permitted us to study patients with foreign body aspiration who were admitted to their departments. Walter S. Meyer, MD, of the Carmel Hospital, Haifa, assisted in the preparation of this manuscript.

Incidence of Meconium Abnormalities in Newborn Infants With Cystic Fibrosis

Beryl J. Rosenstein, MD, Terry S. Langbaum

• Review of the newborn nursery notes of 87 infants who had cystic fibrosis without meconium ileus (MI) indicated that 12 of them had clinical features consistent with the meconium plug syndrome (MPS). This high incidence of meconium abnormalities suggests that MI and the MPS probably represent different gradations of the same underlying pathologic abnormality. The findings further suggest that a quantitative pilocarpine iontophoresis sweat test be performed in every newborn infant with any type of meconium abnormality, including the spontaneous passage of meconium plugs.

(*Am J Dis Child* 134:72-73, 1980)

Meconium ileus (MI), in which there is obstruction of the small bowel by sticky meconium, has been reported to occur in approximately 7% of newborn infants with cystic fibrosis (CF).[1] The meconium plug syndrome (MPS), in which there is transient distal colonic obstruction associated with the passage of meconium plugs, has also been reported in CF.[2,3] It has been suggested[3] that MI and MPS may represent different manifestations of the same underlying pathologic abnormality: both are related to the presence of abnormal meconium and differ only in the site and severity of obstruction. If this hypothesis is correct, the frequent occurrence of MI in infants with CF and the apparent rarity of MPS is curious. The purpose of the present study, therefore, was to examine the nursery records of patients with documented CF to determine the incidence of all types of meconium abnormalities in the newborn period in this group of patients.

Reprint requests to Johns Hopkins Hospital, 601 N Broadway, Baltimore, MD 21205 (Dr Rosenstein).

SUBJECTS AND METHODS

From July 1, 1973, through November 30, 1978, 149 patients with CF were seen at the Johns Hopkins Hospital, Baltimore. The diagnosis of CF was based on characteristic clinical features and a positive quantitative pilocarpine iontophoresis sweat test (Cl^- concentration >60 mEq/L). Of the 149 patients, 13 (8.7%) had MI. An attempt was made to obtain the newborn nursery records of the remaining 136 patients. Because of problems with record retrieval, however, including lost records and incomplete nursery notes, we were able to use the records of only 87 of the 136 patients. Of these 87 patients, 12 had features consistent with the MPS in the newborn period (Table). Of the 12 infants, seven had abdominal distention, five had vomiting, and five had palpable abdominal masses. Six were treated by the insertion of rectal tubes, suppositories, or enemas. Three infants (patients 3, 4, and 12) passed meconium plugs or abnormal meconium but had no associated problems or abnormal findings. At the time the diagnosis of CF was established, the parents of only five of the 12 patients gave a history of any intestinal problem in the nursery.

RESULTS

Meconium ileus occurred in one of 12 black patients and in 12 of 137 white patients. Among patients without MI, a picture consistent with the MPS occurred in three of five black patients and in nine of 82 white patients. All 75 infants without evidence of meconium obstruction passed their first meconium stool within 36 hours. A review of the newborn nursery notes of 100 infants discharged from two full-term nurseries in Baltimore indicated that all infants passed a meconium stool by 36 hours of age, and in no instances were meconium plugs or abnormal meconium described.

COMMENT

The MPS may occur in association with prematurity,[4] hypotonia,[5] hypermagnesemia,[6] respiratory distress syndrome,[7] sepsis,[7] and hypothyroidism,[4] and as the earliest manifestation of Hirschsprung's disease[4,8] and CF.[2,3] Our findings confirm that the MPS may be the earliest manifestation of CF. It has also been stated[9,10] that newborn infants with CF may pass plugs of abnormal meconium, either in a spontaneous fashion or in response to enemas or digital rectal examination. However, the incidence of these plugs and details of such cases have not been reported. In the present series, the occurrence of meconium abnormalities consistent with the MPS in 12 of 87 newborns with CF but without MI is striking. There was a wide range of manifestations, including three infants who passed abnormal meconium without associated problems, six infants who had abdom-

Patients With Findings Consistent With the Meconium Plug Syndrome

Patient/ Race	Description of Meconium	Distention*	Vomiting*	Treatment	Age at Diagnosis of CF
1/B	Large meconium plugs	+	+	Enemas	1 mo
2/W	Meconium plugs, hard gummy meconium	+	+	. . .	4½ mo
3/W	2 Meconium plugs passed first day	—	—	. . .	2½ yr
4/W	1 Meconium plug passed day 2	—	—	. . .	5 mo
5/W	Large meconium plugs, palpable sausage-shaped abdominal masses	+	—	Rectal tube, enemas	1 wk
6/W	Large meconium plugs, palpable fecal masses	—	+	Rectal suppositories	3 mo
7/W	Large meconium plug, palpable abdominal masses	+	+	Nasogastric tube, enema, rectal suppositories	3 mo
8/B	Meconium plug, palpable abdominal masses	+	—	. . .	6 mo
9/W	Palpable sausage-shaped abdominal masses	+	—	. . .	2½ yr
10/B	Delayed passage of meconium, no description of meconium	+	—	Nasogastric and rectal tubes	3 yr
11/W	Large mucus plug with meconium stool	—	+	Enema	4 mo
12/W	3 Dark-green "glue-like" stools	—	—	. . .	18 mo

* + indicates present; —, absent.

inal distention *or* vomiting, and three infants who had abdominal distention *and* vomiting. Although a contrast enema was performed in only one of these infants (patient 1), the transient nature of the obstruction and the uncomplicated course are more consistent with the MPS than with MI. This spectrum of abnormalities, from the spontaneous passage of plugs of abnormal meconium to the full-blown picture of MI supports the hypothesis that the MPS and MI may represent gradations of the same underlying pathologic abnormality, differing only in degree of severity and site of obstruction.

The etiology of the meconium abnormalities seen in these patients remains unclear. The MPS[11] and MI[12] have been associated with pancreatic exocrine deficiency in the absence of CF, and MI has been described in infants with CF in whom there was widespread mucous gland hyperplasia of the intestinal tract but no histologic evidence of pancreatic involvement.[13] It is possible, therefore, that the meconium abnormalities seen in our patients were due to a combination of abnormal mucoprotein secretions by the intestinal glands and pancreatic exocrine deficiency.

It is of interest that the parents of only five of the 12 infants with meconium abnormalities other than MI were aware that there had been an intestinal problem during the newborn period. This may account for the "apparently" low incidence of MPS in infants with CF. In three of the cases in which the parents were unaware of a problem, the infants passed abnormal meconium but had no associated symptoms and required no therapy. In four cases, however, the infants had distention and/or vomiting. Although the number of cases is small, the occurrence of meconium abnormalities in at least four of 12 black patients is pertinent in view of the high incidence of meconium ileus equivalent reported in black patients with CF.[14]

Review

Trace Elements in the Fetus and Young Infant

II. Copper, Manganese, Selenium, and Chromium

Jonathan C. L. Shaw, FRCP

The trace elements are so called because they constitute less than 0.01% of the weight of the human body; however, despite their relative scarcity, their atoms are present in large numbers and each is believed to play an important role in human growth and development. For example, chromium is perhaps one of the least abundant trace elements in the body and yet even a single hepatocyte contains about 4.5 million atoms of this element. The name "trace element" is, of course, quite arbitrary and survives from the time when early investigators were experiencing great difficulties in measuring these substances; the introduction of more sophisticated techniques has resulted in an enormous increase in our understanding of the role these elements play in metabolism.

This review deals with zinc, copper, manganese, selenium, and chromium. The amount of space devoted to each element is not intended to correspond to its importance in metabolism, but rather to reflect the extent of our current knowledge. This review is being published in two parts; part I, published in the previous issue, dealt with zinc, while part II, which follows, deals with copper, manganese, selenium, and chromium.

COPPER

Though it has been known for more than 100 years that copper is a component of hemocyanin, the respiratory pigment of snails,[1] its possible significance in human metabolism was not appreciated until 1928, when Hart et al[2] showed copper to be an essential nutrient for the rat. Copper is now known to be a component of a number of copper metalloenzymes.[3,4] These enzymes generally bind between 1 and 8 gram-atoms of copper per mole, and the presence of copper is essential for their enzymic activity. The function of the copper seems to be related to its ability to engage in oxidation reduction reactions ($Cu^{2+} \rightleftharpoons Cu^{+}$).

Copper Enzymes

A list of some copper enzymes is given in Table 1. Ceruloplasmin is a blue glycoprotein (molecular weight, 160,000) and contains 8 gram-atoms of copper per mole (0.32%). It is synthesized in the liver and is released into the circulation, where it accounts for the majority of the plasma copper. In the newborn pig, ceruloplasmin exists in two forms that differ in their enzymatic activity and copper content. The neonatal type, predominant at birth, remains constant, whereas the adult type increases postnatally.[5] Osaki et al[6] have advanced the hypothesis that ceruloplasmin is an important ferroxidase that facilitates the release of iron from iron stores by oxidizing ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}) prior to its incorporation into plasma transferrin.

Cytochrome C oxidase is the terminal enzyme of the cytochrome chain and contains 1 gram-atom of copper per mole of haem A. It is located in the mitochondria and, as an electron donor, catalyzes the reduction of molecular oxygen to water. This enzyme therefore occupies a vital position in energy metabolism. Its concentration falls in the brain and liver of the copper-deficient animal and may account *inter alia* for the hypothermia of copper deficiency.

Lysyl oxidase catalyzes the cross linking of the polypeptide chains of collagen and of elastin. The enzyme has a molecular weight of 60,000 daltons and contains 0.14% copper by weight.[3] Tyrosinase catalyzes the first two steps in the synthesis of melanin, and genetically determined absence of this enzyme results in albinism.

Copper Deficiency in Animals

Anemia and neutropenia are regular features in copper-deficient animals. The early work of Hart and colleagues[2] has been reviewed by Lardy.[7] They showed that the anemia of rats fed on a milk diet from weaning could not be corrected by administration of iron alone, but that it was cured by administration of the ash of liver, lettuce, or corn. By precipitating the copper from acid extracts of the ash with hydrogen sulfide, they were able to show that it was the copper in the ash that was essential for the full reversal of the anemia. Apart from its association with iron in cytochrome C oxidase, copper interacts with iron metabolism at two points: the release of iron from iron stores, and the incorporation of iron into haem.

According to the Osaki hypothesis,[6] ceruloplasmin is a ferroxidase that is essential for the mobilization of iron from iron stores. This has been studied in newborn pigs and the work has been recently reviewed by Lee et al.[8] In copper-deficient swine, ceruloplasmin levels fell to less than 1% of normal and there was an associated fall in serum iron levels. Iron absorption was diminished and iron accumu-

lation was observed in the intestinal mucosal cells and adjacent macrophages, suggesting a difficulty in release of iron from the mucosal cells. Injection of parenteral iron in the form of colloidal iron oxide or damaged erythrocytes resulted in trapping of the iron in the iron stores and reticuloendothelial cells of these copper-deficient animals. Injection of ceruloplasmin then resulted in a prompt release of iron from the iron stores, as judged by a rise in plasma iron concentration. These data are consistent with the role of ceruloplasmin as a ferroxidase. However, the extreme variability of ceruloplasmin oxidase activity among species[9] and its virtual absence in the plasma of the turkey and the peacock[10] and certain crocodiles[11] shows that much remains to be discovered.

There is now much evidence to link copper with the synthesis of haem that takes place within the mitochondria and involves the enzyme ferrochelatase and the precursors protoporphyrin IX and Fe^{2+}. Since both iron and protoporphyrin accumulate within the erythroid cells of copper-deficient animals, the precursors of hemoglobin are not lacking in the marrow, and failure to release iron from the iron stores cannot, therefore, account entirely for the anemia of copper deficiency. Copper deficiency is thought to interfere with haem synthesis in three ways: by diminishing iron transport into the mitochondria,[12] by inhibiting the activity of ferrochelatase,[13] and possibly by reducing the concentration of the copper-iron enzyme cytochrome C oxidase. Lee et al[8] reviewed their evidence that an intact cytochrome chain is necessary for the synthesis of haem; uncoupling oxidative phosphorylation with 2,4-dinitrophenol did not inhibit haem synthesis, indicating that electron transport rather than adenosine triphosphate synthesis was the essential function. They postulated that the cytochrome chain, by providing a source of electrons, was necessary to reduce ferric (Fe^{3+}) iron to its ferrous form (Fe^{2+}) prior to incorporation into protoporphyrin IX. It seems, therefore, that events in the mitochondria may be more important determinants of the anemia of copper deficiency than diminished ferroxidase activity in the plasma. Neutropenia was observed by Wintrobe et al[14] in copper-deficient swine and has been reported in many species since, including man; however, its cause is unknown.

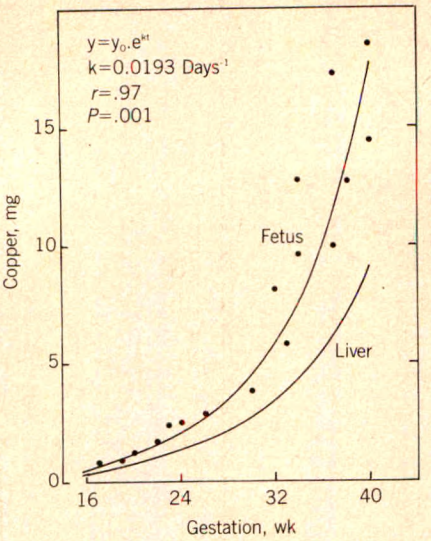

Fig 1.—Changes in the copper content of the human fetus and fetal liver with gestation.[18,19]

Collagen and Elastin Synthesis

In copper-deficient animals, aneurysms of major vessels readily develop, and they may cause death from hemopericardium or from hemothorax as a result of aortic rupture.[1] The collagen and elastin of these animals has been found to be abnormal, with reduced cross linking and consequent reduction in strength and elasticity. These effects result from the reduced activity of lysyl oxidase.[3] The bones become brittle and fracture easily, and roentgenograms show blurring and cupping of the metaphysis reminiscent of scurvy. The disorder of collagen metabolism is partly responsible, but reduced activity of ascorbic acid oxidase (another copper enzyme) may also play a part. Hair abnormalities described as "steely hair" are found in copper-deficient animals and are attributed to defective cross linking of the keratin molecule. Depigmentation of hair, so striking in copper-deficient black sheep, results from impairment of tyrosinase activity.

Effects of Copper Deficiency During Gestation

Copper deficiency during pregnancy in sheep results in the ataxic disease "swayback" or "enzootic neonatal ataxia" in the newborn lamb. In affected sheep, there is extensive demyelination of the CNS, and the brain mitochondria show depletion of cytochrome C oxidase.[1] These changes are observed in a number of other species.[15] Anormalities in elastin occur and extensive changes in the myocardium of copper-deficient rat pups have been reported with depletion of myocardial cytochrome oxidase.[16,17]

Copper in the Human Fetus and Newborn

Copper must enter the embryo from the earliest moments of gestation, but little seems to be known about its role in this early period. Figure 1 shows the accumulation of copper by the human fetus.[18] At term, about half the copper in the body is present in the liver,[19] where it is bound to a protein recently identified as a metallothionein.[20,21] After birth, the concentration of copper in the liver falls as the copper is used for growth, though the total amount ultimately increases because of the increase in size of the organ.[18] Estimates of the daily rate of accumulation of copper by the human fetus are given in Table 2. The value of 0.051 mg/kg/day for a fetus growing along the 50th percentile is lower than previous estimates,[22] which were based on the exponential regression analysis given in Fig 2, and did not take into account the unusually high body weight of the mature fetuses in Widdowson's series.[18] These revised rates of accumulation correspond quite closely to those recommended for intravenous feeding of preterm infants.[23]

Copper in Blood

In adults, about 49% of the copper in whole blood is in the RBCs, where the concentration is about 110 μg/dL of RBCs.[14] Unlike the plasma copper, there is very little species variation in the RBC copper[10]; about 60% is present in the enzyme superoxide dismutase. The concentration of this enzyme is high in RBCs of the fetus and falls

Table 1.—Some Copper Enzymes

Enzyme	Source
Cytochrome C oxidase	Mitochondria
Superoxide dismutase	Erythrocytes

32	0.071	0.094	0.125
34	0.088	0.120	0.161
36	0.112	0.148	. . .

*This is a revision of previous estimates.[22] For these calculations, the amount of copper in the fetal bodies was calculated from the concentrations reported by Widdowson and Dickerson[18] and the body weights reported by Lubchenko et al.[103] The rates were calculated by exponential analysis. The specific accumulation rates for infants growing along the different percentiles are as follows: tenth percentile, 0.055 mg/kg/day; 50th percentile, 0.051 mg/kg/day; 90th percentile, 0.043 mg/kg/day (previous estimates were 0.078 to 0.092 mg/kg/day[22]).

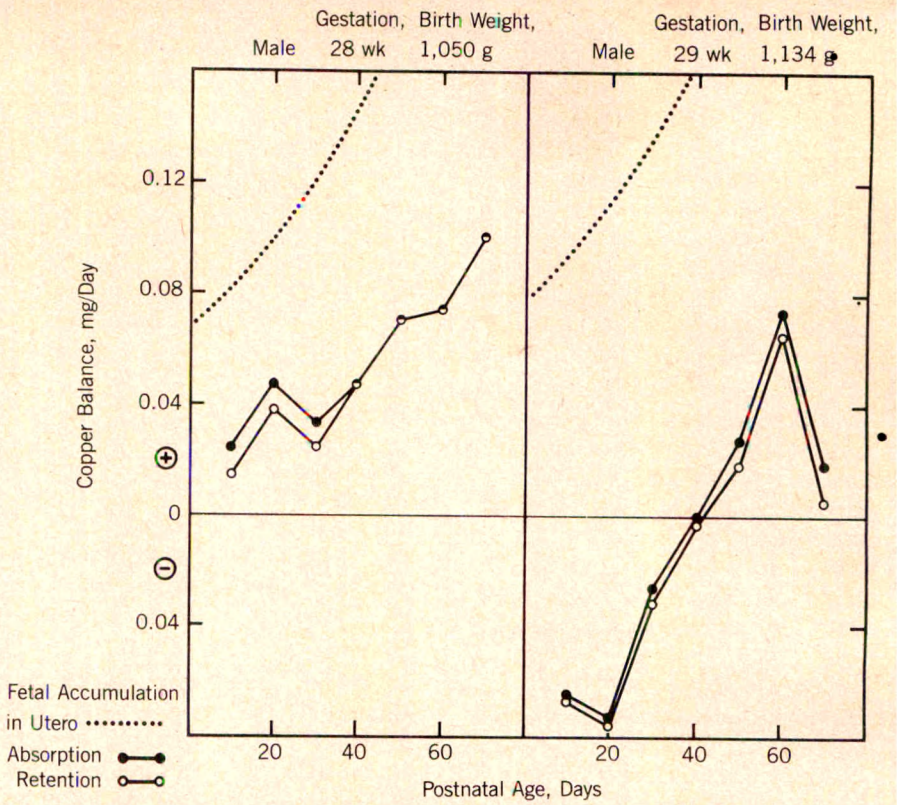

Fig 2.—Contrasting examples of copper balance in two preterm infants.[52] Balances commenced on tenth day of life and lasted three days. They were repeated every ten days until infant was discharged home. Estimated fetal accumulation rate is given for comparison.[103]

toward term.[24] The remaining 40% of the RBC copper is in a labile pool in equilibrium with plasma copper.[4] In plasma, about 96% of the copper is present as ceruloplasmin[25] and only about 8% of the ceruloplasmin is present as apoceruloplasmin.[26] In newborn infants, Henkin et al[27] showed that 86% of the plasma copper was retained by a filter that excluded particles "substantially in excess of 50,000 daltons." Hence, ceruloplasmin-bound copper in newborns may be a smaller percentage of the total than it is in adults. To my knowledge, no attempt to characterize human fetal or neonatal ceruloplasmin has yet been reported.

The majority of the copper not bound to ceruloplasmin is bound to serum albumin. The amino acid sequence of the albumin binding site has recently been determined and a structure for it proposed, and though there are species differences, the capacity to bind copper seems dependent on the histidine residue at the binding site.[28,29] The albumin-bound copper is relatively labile and is in equilibrium with copper bound to amino acids and to oligopeptides. Blood concentrations of copper and ceruloplasmin are given in Table 3. Plasma copper levels are higher in women than in men and both the total copper and ceruloplasmin levels virtually double in women taking oral contraceptives. During pregnancy, copper and ceruloplasmin levels rise. The highest levels are seen at term and fall to normal by about 6 weeks after delivery. Paradoxically and in contrast to zinc, the total copper and ceruloplasmin levels are low at birth in full-term infants and may rise to above adult levels between 1 and 6 years of age (Table 4).

Copper in Milk

The copper content of human milk is given in Table 5. According to the data of Nassi et al,[30] the concentration of copper, unlike that of zinc, seems to be no higher in colostrum than in mature milk. However, Hambidge[31] has recorded a mean value of 119 μg/dL on days four to seven after birth, and Cavell and Widdowson[32] observed a mean value (± standard deviation) of 68 ± 8 μg/dL on days five to eight after birth. The copper concentration seems to fall toward the end of lactation. At an intake of 150 mL/kg/day of mature milk, an infant would receive about 60 μg/kg/day. Cavell and Widdowson[32] showed that full-term infants receiving breast milk were in negative balance, averaging −0.009 mg/kg/day (range, +0.029 to −0.066 mg/kg/day). Kleinbaum[33] reported similar results. How long these negative balances persist is not known.

Copper Absorption and Excretion

Copper is thought to be absorbed complexed with amino acids by an active process. Some of the copper in the mucosal cell is associated with

metallothionein. The copper is transported in the blood to the liver, where ceruloplasmin synthesis takes place. The principal route of excretion of copper from the body is in the bile, where copper is found complexed to proteins and low-molecular-weight ligands. The protein-bound copper in bile is apparently poorly reabsorbed, though the remainder enters into an enterohepatic circulation.[4]

Copper Deficiency in Infants

Following up the experimental work of Hart et al,[2] Elvehjem[7,34] showed that copper might be effective in treating anemic infants. However, these studies included neither measurements of plasma copper nor an untreated control group, and though copper appeared to be effective, this fact was not really established. This work was followed by a number of reports of hypocupremia in anemic infants, some of whom responded to therapy with copper.[35-37] Recently, Graham and Cordano[38] have reviewed their work on copper deficiency in malnourished infants rehabilitated on a cow's milk diet low in copper. They found a fall in copper and ceruloplasmin levels to be the earliest change, the latter falling to almost undetectable levels. Neutropenia and anemia followed, the latter being typically resistant to therapy with iron. Later, bone changes reminiscent of scurvy developed, with occasional fractures. Since this work was published, there have been several reports of hypocupremia and copper deficiency developing in patients receiving copper-free total parenteral nutrition.[39-46] The principal features of the syndrome are now well described and are summarized in Table 6.

The Preterm Infant

To my knowledge, there are now three case reports in the literature of well-documented copper deficiency in small preterm infants fed a milk diet low in copper[47-49] and others where it was suspected but not established.[50,51] In the proven cases, the infants all weighed less than 1,200 at birth and their deficiency state developed between three and six months postnatally.[47-49] In addition, four of the 14 cases of hypocupremia reported by Schubert and Lahey[36] were premature infants. The reasons for the particular vulnerability of the preterm infant have been discussed earlier. Breast milk given at 200 mL/kg/day provides copper just in excess of the estimated fetal accumulation rate (Table 5), but not all of it is absorbed. Dauncey et al[52] have shown that the preterm infants they studied given breast milk were, on average, in negative balance until the 35th day of life, and even those infants in positive balance never equalled intrauterine accumulation rates (Fig 2). This confirms the earlier observations of Kleinbaum,[33] who found negative copper balances in all the low birth weight infants he studied.

The changes in plasma copper levels in preterm infants measured in my laboratory are given in Fig 3. Unlike the full-term infants, the plasma copper level was high at birth and tended to fall steadily to quite low values. The changes in serum ceruloplasmin levels closely resembled the changes in total copper levels. These results are preliminary and their exact significance is not yet known. Does this fall in copper level, for instance, reflect a deficiency, or is it part of a normal decline resulting in the usual low values at term?

Menkes' Kinky-Hair Disease

This is an X-linked, recessively inherited disease first described by Menkes et al.[53] It is characterized by many of the features of copper deficiency, but apparently without neutropenia and anemia.[54] There are pili torti, typical bone changes, arterial intimal changes, seizures with developmental regression, hypothermia, and the patients generally die before the age of 2 years. Plasma copper and ceruloplasmin levels are very low[26,54-58] and copper absorption is defective.[54,57] Williams et al,[54] by infusing copper as a copper histidine complex, were able to raise plasma copper and ceruloplasmin levels to normal, but, though the

Table 6.—Syndrome of Copper Deficiency in Infants

Clinical Features
Psychomotor retardation
Hypotonia
Pallor and hypopigmentation
Prominent scalp veins in palpable periosteal depressions
Hepatosplenomegaly
Roentgenographic changes with osteoporosis, blurring and cupping of metaphysis; subperiosteal new bone formation; fractures
Sideroblastic anemia, resistant to iron therapy
Bone marrow shows vacuolated erythroid and myeloid cells with iron deposition in vacuoles
Neutropenia
Plasma copper level usually < 12 μg/dL
Serum ceruloplasmin 2-10 μg/dL

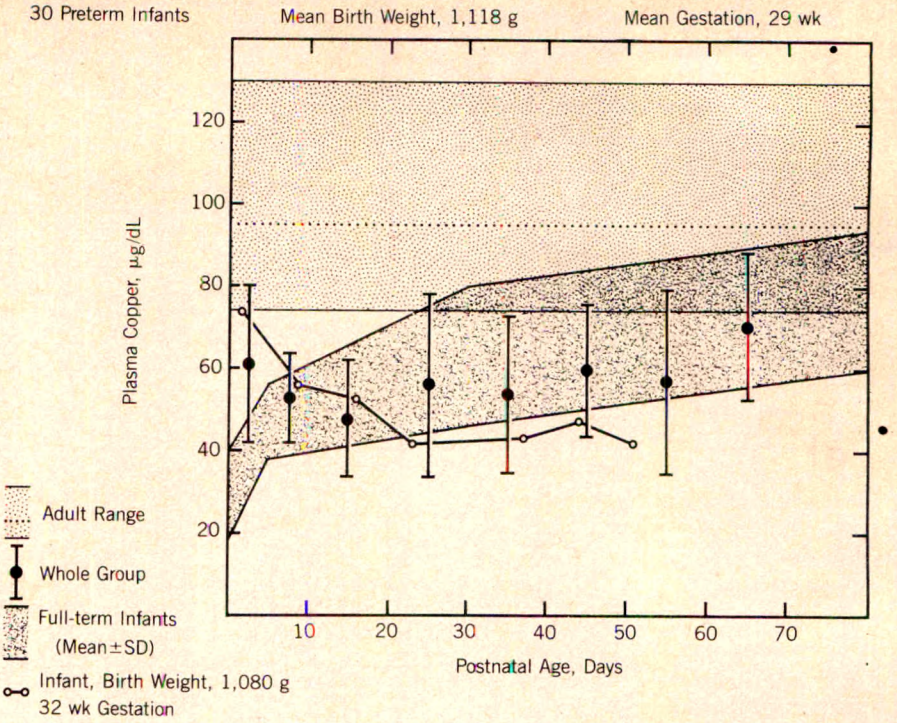

Fig 3.—Changes in plasma copper levels, after birth, in preterm infants compared with values for full-term infants.[102] Adult range in this figure is based on measurements in 20 healthy adult men.

fractures healed, there was no amelioration of the other features of the disease. Since cultured fibroblasts from cases of Menkes' disease handle copper quite differently than do normal cells, it seems likely that the defect is not confined to copper absorption.[59]

Wilson's Disease

Wilson's disease[60] is an autosomal-recessive condition characterized by progressive cirrhosis of the liver, renal malfunction with amino aciduria, glycosuria, neurological degeneration, and Kayser-Fleischer rings in the cornea. These, the major manifestations of the disease, are secondary to the pathological accumulation of copper in the tissues, which results from diminished excretion of copper in the bile.[61,62] The serum ceruloplasmin level is reduced, but is rarely less than 5% of normal.[25] Though the total plasma copper concentration is reduced, because of the low ceruloplasmin level, the labile albumin-bound fraction is increased and accounts for the high urinary copper excretion. A metallothionein with high affinity for copper has been isolated from cases of Wilson's disease,[63] but this finding seems not to have been confirmed. Such a substance is unlikely to account for all the features of the disease. The most effective treatment of Wilson's disease is the use of the chelating agent penicillamine,[64] which, by reducing the total body copper, can arrest the consequences of copper accumulation. However, care is required to avoid zinc deficiency during treatment.[65]

MANGANESE

The metabolism of manganese has been reviewed by Leach.[66] Manganese is a component of comparatively few metalloenzymes; these include pyruvate carboxylase and mitochondrial superoxide dismutase. However, manganese activates a number of enzymes, particularly the glycosyltransferases that are involved in the synthesis of polysaccharides and glycoproteins. The features of manganese deficiency, namely impaired growth, skeletal abnormalities, depressed reproductive function, and ataxia in the newborn,[1] seem to be similar in all species studied. The skeletal abnormalities are thought to be due principally to defective mucopolysaccharide synthesis affecting chondrogenesis. Manganese deficiency in pregnant rats induces profound ataxia in the young.[67] Disturbed ossification of the otic capsule and malfunction of the semicircular canals are responsible for this ataxia. The timing of the deficiency is critical, since provision of manganese to the deficient pregnant rat on day 14 (term, 22 days) completely prevented the defect, whereas manganese supplements given on day 18 had no effect.[67] The ataxia of this deficiency is indistinguishable from a specific genetically determined ataxia due to an otolith defect in pallid mutant mice, which can be prevented by the administration of pharmacological amounts of manganese to the pregnant dams.[68]

The amount of manganese present in the human fetus is not known, though the manganese content of the fetal liver has been analyzed.[19] Human milk contains 1.2 to 2.0 μg of manganese per dL and cow's milk between 3.2 to 5.2 μg/dL.[69] The breast-fed full-term infants studied by Widdowson[70] aged 5 to 8 days were in negative manganese balance. The regulation of manganese in the body is by controlled excretion in the bile,[66] but it is not known whether the negative balances in babies represent an important failure in homeostasis or not. Very little is known about manganese deficiency in man. The only reported case in man exhibited a mild dermatitis, slight reddening of hair, and

depressed vitamin K-dependent clotting factors that did not respond to therapy with vitamin K.[71] Among infants, the preterm infant and those receiving total parenteral nutrition would seem to be the most at risk, and evidence for manganese deficiency should be sought in such cases.

SELENIUM

The importance of selenium as a nutrient was first suspected when it was shown that administration of either selenium or vitamin E could prevent hepatic necrosis of nutritional origin in rats.[72] In 1969, Thompson and Scott[73] separated the effects of selenium deficiency from those of vitamin E deficiency and established selenium as an essential nutrient in vertebrates. To date, the only established function of selenium in man is as a component of the enzyme glutathione peroxidase (GSH-px).[74] This enzyme is distributed widely in the cells of the body and in particular is present in high concentration in the RBCs and the liver. The human enzyme is a tetramer with a molecular weight of 95,000 daltons and contains 4 gram-atoms of selenium per mole.[75] It catalyzes the reduction of hydrogen peroxide using glutathione as a proton donor and functions to protect the cell against peroxide-induced damage. This property, together with its capacity to catalyze the reduction of lipid and other hydroperoxides, is perhaps its principal function in the cell, and accounts for the evident overlap in function with vitamin E, another important antioxidant. Recently, a nonselenium-dependent GSH-px has been described in rat liver.[76] These functions may be of particular significance to phagocytic cells, where peroxides and highly reactive forms of oxygen such as the superoxide radicle[77] are generated during the process of phagocytosis and killing of the ingested organisms. This capacity of the phagocyte to generate the superoxide radicle may be related to the absence of copper-zinc superoxide dismutase from the cytosol.[78]

Virtually nothing seems to be known about selenium in human fetal development. Numerous studies of GSH-px in RBCs have shown lower activities in the newborn and premature infants than in adults.[79-85] Rudolph and Wong[86] have confirmed these observations and have shown that both plasma and RBC selenium and GSH-px levels were lower in the cord blood of full-term infants than in adults. In preterm infants, cord-blood selenium levels were no lower than in full-term infants,[82,83] but in two low-birth-weight infants in whom serial measurements were made, low levels were observed that persisted for several months[82]; however, the functional importance of this trend is not known. The recent report that newborn rats exposed to high concentrations of oxygen adapt with an increase in levels of GSH-px and superoxide dismutase in the lungs suggests that these enzymes play an important part in the capacity of the newborn to resist free-radical damage.[87]

The concentration of selenium in breast milk is reported as being 1.2 to 5.0 μg/dL,[88] but it may be ten times less than this.[89] The concentration in cow's milk is lower than in breast milk and varies with the selenium content of the pastures.[88] Nothing is known about selenium homeostasis in newborn infants, but low levels of plasma selenium have been observed in children on total parenteral nutrition,[90] and low levels of selenium and GSH-px have been found in children on a diet for phenylketonuria or maple syrup urine disease.[91]

CHROMIUM

Chromium has only recently been recognized as being an essential element in man. The subject has been extensively reviewed by Mertz et al.[92-94] Chromium is present in all tissues of the body, but is present in high concentrations in nucleic acids and in certain tissues, such as the caudate nucleus. It forms complexes typically exhibiting a low rate of ligand exchange, which would seem to make it an unsuitable component of the active site of enzymes and more compatible with a structural function, for instance stabilizing the tertiary structure of nucleoprotein or binding an enzyme to its active site. Chromium deficiency in animals is characterized by impaired glucose tolerance with fasting hyperglycemia, glycosuria, hypercholesterolemia, corneal opacities, and impaired growth. This state can be reversed by giving trivalent chromium (Cr^{3+}) or by much smaller amounts of Cr^{3+} given as an organic complex known as glucose tolerance factor (GTF). This substance has been extracted from a brewer's yeast, *Saccaromyces carlsbergensis*, and has a molecular weight of about 500 daltons. Each molecule contains one atom of chromium in a complex consisting of two nicotinic acid molecules, and one each of glycine, cysteine, and glutamic acid. After the removal of the amino acids (which make the complex water soluble), the di-nicotinato tetra aquo compound is thought to break down the intrachain disulfide bridge in the A chain of the insulin molecule, to effect a connection between the insulin molecule and sulfhdryl groups on the membrane receptor. Thus, the GTF may form a stable bridge between insulin and the membrane receptor.[93]

Studies in elderly diabetics[95] and in children recovering from protein-calorie malnutrition[96-98] have shown that Cr^{3+} administration has been associated with improvement of glucose tolerance. More recently, Jeejeebhoy et al[99] have described an adult patient receiving total parenteral nutrition for more than five years in whom there developed an impairment of glucose tolerance and a peripheral neuropathy that was reversed by chromium administration. It is not known how important chromium is for fetal development. In the rat, inorganic ^{51}Cr crosses the placenta very poorly, but ^{51}Cr-labeled GTF extracted from brewer's yeast crosses readily into the fetus.[92] In man, nothing is known about the placental transport of chromium other than that it occurs. Chromium is present in the liver of the human fetus[19] and the concentration in the whole fetus is said to decrease during pregnancy and after birth.[92] This is perhaps reflected in the falling hair chromium concentrations of young infants.[100] It is perhaps worth noting that because of the prevailing and analytical prob-

lems, reported values from chromium should be regarded as provisional.[101]

CONCLUSION

Current knowledge of trace-element metabolism is increasing rapidly with the application of new techniques. Though trace elements are numerous in the body and act at many levels of metabolism, the effects of deficiencies of some of these elements on fetal and neonatal development are only just beginning to be understood. The preterm infant, because of low body stores, inadequate provision of nutrients in the milk, and immature intestinal function, seems particularly at risk of trace mineral deficiency, and research in this area might be repaid with a worthwhile reduction in morbidity.

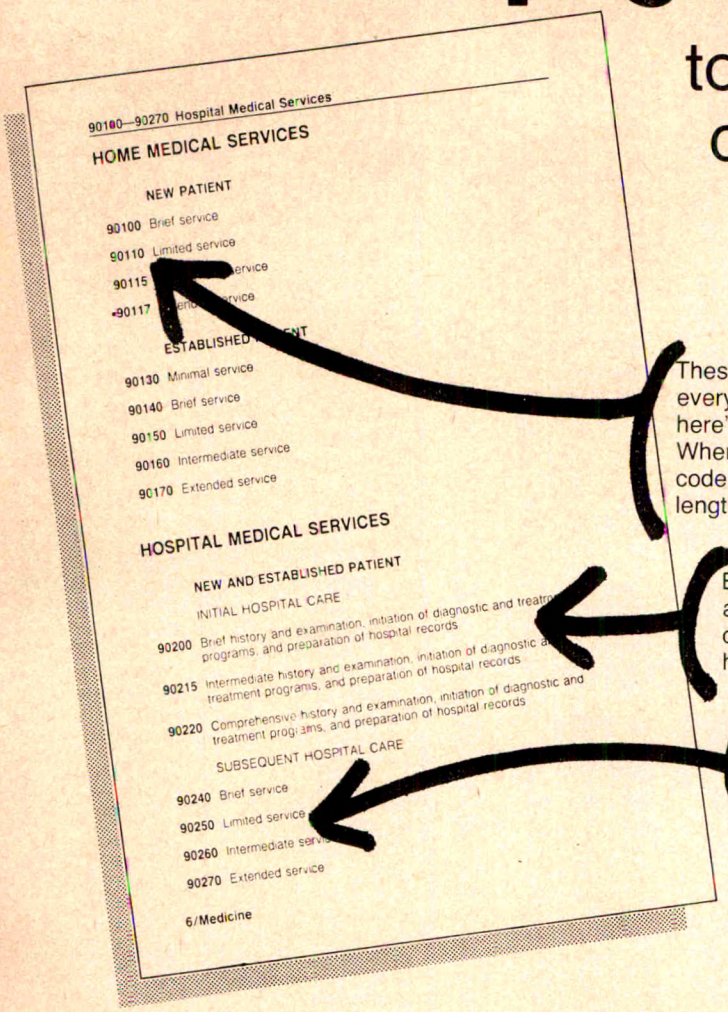
We took a page out of CPT-4

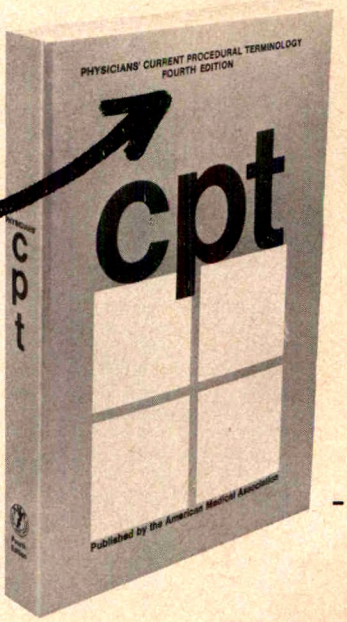
to show you how it can cut your administrative reporting time 50% or more!



These five digit numbers are CPT codes. There's one code for every medical, surgical, and diagnostic service you perform. Now here's where CPT can really save you a lot of time—and money. When you prepare a medical report, you merely insert the CPT code that identifies the procedure—eliminating the need for lengthy descriptions of procedures.

Each procedure is listed and described separately, clearly, accurately and each one has its own five-digit identifying code. After the first few times you've used the code, you'll have it memorized and be able to jot it down automatically.

CPT is a coding system that provides a uniform language among physicians, patients, and third parties.



This fourth edition of **Physicians' CURRENT PROCEDURAL TERMINOLOGY** is the most comprehensive and current system available for naming, coding, and reporting medical procedures and services. It incorporates over 2,000 new and revised procedures.

New Updating Service is available at no extra cost. To insure your CPT stays up to date as new terminology is added, you can receive new and revised procedures on a regular basis. Updates are on self-adhering pages to be affixed to the pages they replace.

Order today! Buy two—one for yourself and one for your medical records clerk.

Radiological Case of the Month

Lionel W. Young, MD; Contributed by Michael V. Severson, MD; Edmund C. Burke, MD; Robert R. Hattery, MD

A week before admission, a boy 3 years 3 months of age was referred to our clinic because his abdomen was large and a huge abdominal mass was palpated by his physician.

On admission, the child's height was 96.5 cm, and he weighed 15.9 kg. He seemed to be in good health although his abdomen was greatly distended. His temperature and blood pressure were normal, as were the results of the rest of the physical examination, excluding the abdomen. Palpation of the abdomen showed a large mass that was soft and nontender; its margins were not discrete. No organs were palpable, and there was no edema.

Hemoglobin level, leukocyte and differential cell counts, urinalysis, and roentgenogram of the chest were normal. The levels of urinary vanillylmandelic acid and homovanillic acid were normal. The serum level of creatinine was 0.45 mg/dL. Values for electrolytes, alkaline phosphatase, SGOT, and SGPT were normal.

An excretory urogram (Fig 1) and abdominal aortograms (Fig 2) were done. Surgical exploration was undertaken.

From the Departments of Pediatrics (Drs Severson and Burke) and Diagnostic Radiology (Dr Hattery), Mayo Clinic and Mayo Foundation, Rochester, Minn.

Reprint requests to Department of Radiology, Children's Hospital of Pittsburgh, 125 DeSoto St, Pittsburgh, PA 15213 (Dr Young).

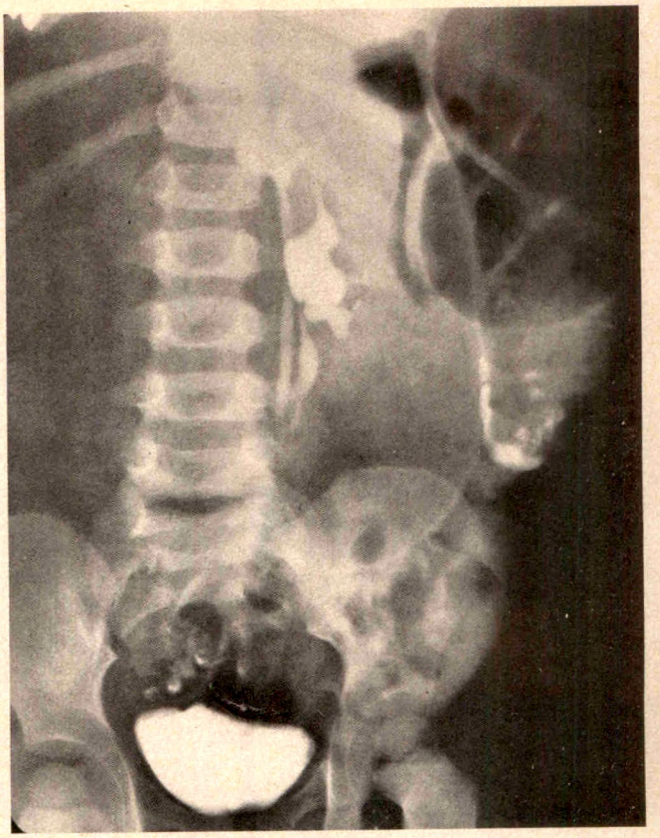

Figure 1.

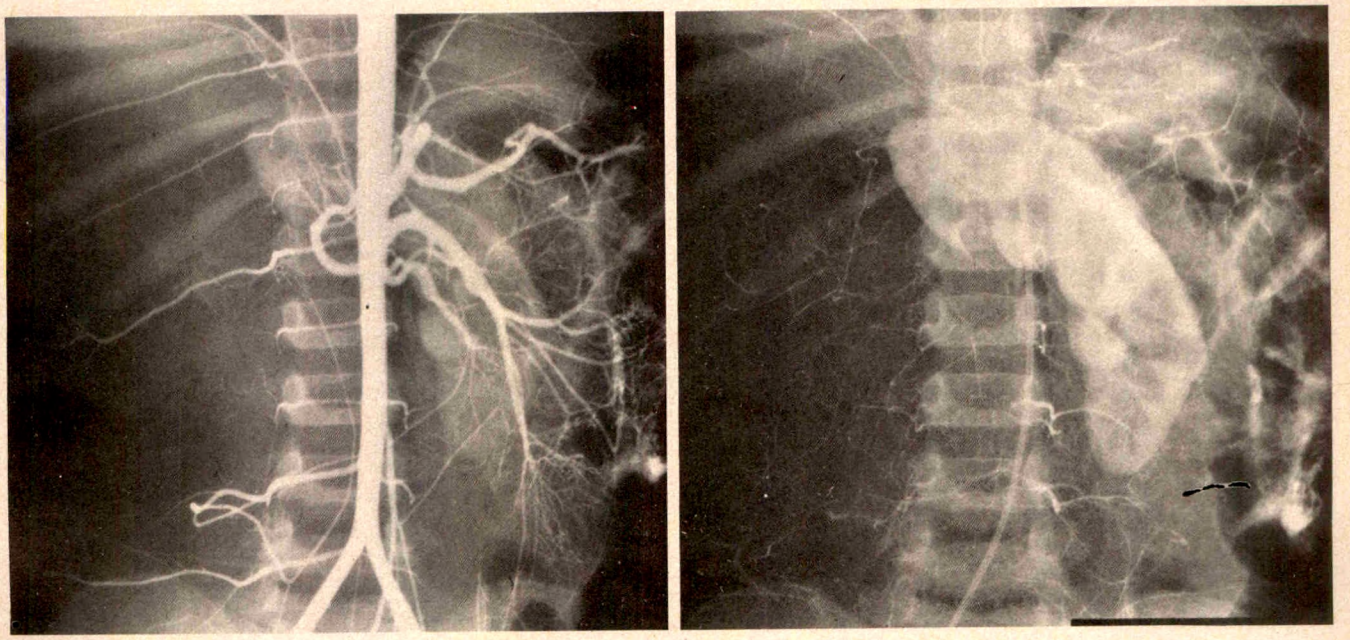

Figure 2.

Denouement and Discussion

Fig 1.—Excretory urogram showing displacement of right kidney superiorly and across midline. Right kidney is displaced but not invaded by mass, and mass does not obstruct ureter.

Fig 2.—Abdominal aortograms showing large tumor in right retroperitoneal space. Left, Major visceral arteries are displaced toward left, and right renal artery is displaced superiorly. Right, Nephrogram phase demonstrates normal renal parenchyma bilaterally.

Fig 3.—Gross lipoma.

Retroperitoneal Lipoma in a Child

Exploration of the right upper quadrant was done transperitoneally through a transverse incision, and a retroperitoneal encapsulated mass was removed. There was no evidence of invasion of adjacent structures, and the kidneys were normal.

The mass weighed 1,870 g (Fig 3). Histologic examination indicated that it was a lipoma. The child has been completely well since the operation five years ago.

Fifteen other instances[1-16] of benign retroperitoneal neoplasms in children have been published, some of which attained incredible size (eg, the heaviest being 2,860 g and the largest being 4,608 cu cm). Histologically, these lesions were essentially lipomas though some had fibromatous or myxomatous elements. Tumors with sarcomatous elements were excluded because of the malignant aspects of such tumors.

Lipoblastomatosis[13] is a separate entity inasmuch as the circumscribed form is generally superficial and the diffuse form is deep, in some instances without continuous capsule and therefore infiltrative. Most patients with lipoblastomatosis were less than 3 years old, and the neoplasms involved the extremities rather than the retroperitoneal area. Chung and Enzinger,[13] however, included two patients with retroperitoneal neoplasms, one patient being a 6-month-old female infant who was well 12 years after its removal.

Irwin et al[16] described a patient with Down's syndrome who died of other causes and whose autopsy disclosed a lipoma weighing 1,750 g. They stated that, whether the neoplasms were removed or not, a slow death usually followed. Their statement is probably erroneous, on the assumption that they were referring to invasive lipoblastomatosis rather than to an encapsulated retroperitoneal lipoma.

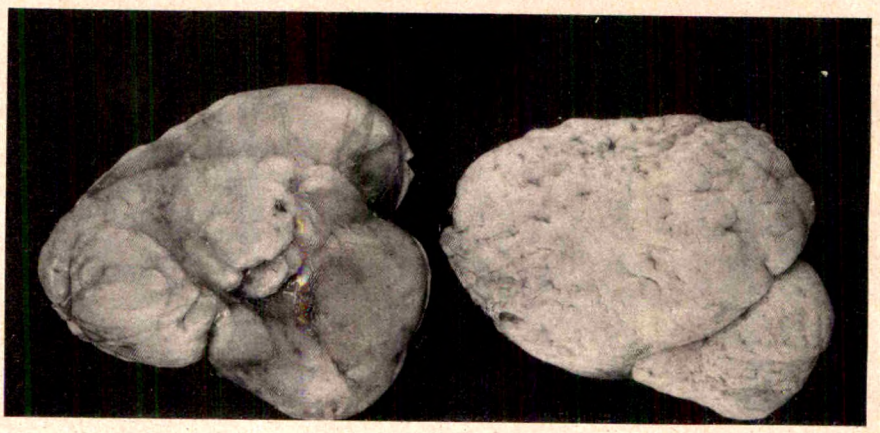

Figure 3.

Current evidence and past experience suggest that a child, well-appearing, free of symptoms, but with a large abdominal mass, should be suspected of having a benign retroperitoneal neoplasm. Such a lesion is surgically curable.

Honor Roll of Reviewers for 1979

The men and women whose names appear below kindly served as reviewers and referees this past year. The diverse nature of the manuscripts we receive, and their large numbers, means that the Editorial Board must rely on outside help if these manuscripts are to enjoy the sort of critical review that they deserve. So we and our readers thank them one and all.—ED.

Pulmonary Veno-Occlusive Disease Appearing as Acute, Recurrent Abdominal Pain

Pulmonary hypertension without associated congenital heart defect is uncommon in children. When it occurs, pulmonary hypertension is usually caused by pulmonary arterial involvement and only rarely will primary pulmonary veno-occlusion be found. The symptom in pulmonary veno-occlusive disease is progressive "breathlessness," dyspnea on exertion.[1-3]

We studied a case of pulmonary veno-occlusive disease whose main symptom was severe, recurrent abdominal pain. As abdominal pain is a common childhood complaint, the associated increasing dyspnea was overlooked and the diagnosis of pulmonary veno-occlusive disease not immediately made.

Report of a Case.—A 6-year-old girl was referred for evaluation of recurrent abdominal pain. She had always been healthy and active. For several months she had had episodes of severe abdominal pain after an upper respiratory tract infection. This pain was sudden, severe, and she would turn pale. She complained that her heart pounded and her breathing was rapid. Sometimes she vomited and was exhausted. Her pain came several times daily. Bowel habits were unchanged and a trial of diet and antispasmodics gave no relief. Previous studies included a normal upper and lower gastrointestinal series and ECG. Her EEG was somewhat abnormal, but anticonvulsants did not abolish the abdominal pain.

When evaluated, she appeared small and chronically ill. Examination results were normal except for the cardiac findings. There was a short basal systolic murmur and finely split second sound with accentuation of the second component in the pulmonic area. Blood pressure was 80/60 mm Hg, right arm lying. Chest roentgenogram showed minimal cardiomegaly, pulmonary vascular obstructive changes, and the B lines of Kerley (Fig 1). Electrocardiogram showed moderate right ventricular hypertrophy. She was given digitalis and diuretics. Findings from all laboratory studies were normal. Echocardiogram ruled out a left atrial mass lesion (left atrial diameter, 2.4 cm; left ventricular diameter, 2.1 cm). Cardiac catheterization showed elevated right ventricular and pulmonary artery pressures and a normal pulmonary wedge pressure (Table). During the angiogram, contrast medium filled the main pulmonary artery promptly with a slow run-off. No left atrial filling defect was seen.

On the basis of the clinical, roentgenographic, and catheterization findings, the diagnosis of pulmonary venoocclusive disease was made. An open lung biopsy was performed. She was alert and responsive after the procedure, but 40 minutes later had a cardiac arrest and could not be resuscitated.

The significant findings on gross examination were limited to the thorax. The root of the pulmonary artery was severely dilated, 3 cm in diameter compared to an aortic root of 1.8 cm. The right ventricle was hypertrophied, the left atrium and the mitral valve were normal. Pulmonary vessels protruded from the sectioned surfaces. The microscopic pattern was fairly uniform within all lobes. Hemosiderin-containing alveolar macrophages were clumped focally. There was diffuse though focal alveolar fibrosis. Occasionally there were plasma cells, lymphocytes, and polymorphonuclear leukocytes both within the thickened alveolar septa and also in minute intra-alveolar foci. Occasional bronchiolar mucous gland hyperplasia was noted. The lymphatics were dilated. On hematoxylin-eosin stained sections, there was diffuse but random intimal fibrosis of the pulmonary venous system. Both venules and larger pulmonary veins were involved. Elastic stains showed focal arterialization of the venous system, ie, development of internal and external elastic lamina. The media were thickened in the involved vessels and there was variable narrowing and occlusion with fibrotic tissue. In many vessels, the lumina were multichanneled, suggesting recanalization (Fig 2). Changes in the pulmonary arterial system were limited to medial hypertrophy. As in the previously reported cases, there was no evidence of venous disease in any other organ of the body. The liver was entirely normal.

Comment.—Pulmonary veno-occlusive disease is a rare condition described by Hora in 1934. It occurs mainly in children and young adults and only 31 cases, to our knowledge, have been described in the literature. Both sexes are involved equally. Patients have gradually increasing dyspnea, first on exertion and then continuously. Physical examination and laboratory findings are usually normal until the process progresses to frank cardiac failure, syncope, and death. The ECG may show right ventricular hypertrophy. The chest roentgenogram shows mild to moderate cardiomegaly. Whereas in primary arterial pulmonary hypertension there is a decrease in pulmonary vasculature, the roentgenogram in pulmonary veno-occlusive disease shows a fine, diffuse increase of the interstitial vascular markings. The interlobar fissures may be seen and the B lines of Kerley are often present. Cardiac catheterization shows an elevated pulmonary artery pressure. Pulmonary wedge pressure may be normal or elevated, depending on whether a normal or involved segment of lung is sampled. The pulmonary arteriogram shows large central arteries and a slow run-off because of poor cardiac output.[1-6]

The differential diagnosis includes arterial pulmonary hypertension, mitral stenosis, left atrial myxoma, cor triatriatum, sclerosing mediastinitis, congenital stenosis of the pulmonary veins, and large vessel thromboembolic disease. At this time, the cause is unknown. Thromboembolic and immune complex disease has been postu-

Cardiac Catheterization Data

Fig 2.—Pulmonary vein with almost total luminal obliteration and two small channels suggesting recanalization (hematoxylin-eosin, ×400).

lated and one case had deposits of IgG and complement scattered along the alveolar walls.[7] An infectious agent as the initiating event cannot be ruled out as there is often a preceding viral-type respiratory infection. The process is self-limiting and not all areas of lung are involved. Fresh thrombi or emboli have never been found on any pathologic section.

We presume that in our patient the severe abdominal pain was caused by acute, periodic congestion of the liver with stretching of the capsule. No tachyarrhythmias were ever demonstrated on the ECG. Exertional dyspnea was not considered important because it was overshadowed by the severe abdominal pain.

The course of pulmonary veno-occlusive disease is progressively downhill. Antibiotics, oral anticoagulants, heparin, corticosteroids, and immunosuppressives have all been tried without success.[1-7] The diagnosis of pulmonary veno-occlusive disease is rarely made antemortem. The combination of progressive dyspnea and roentgenographic findings of pulmonary vascular congestion and the B lines of Kerley in a patient with catheterization evidence of pulmonary hypertension should alert the physician to this entity. These children, like all patients with pulmonary hypertension from any cause, tolerate surgical procedures poorly. If the diagnosis can be established with reasonable certainty, lung biopsy should be avoided. Supportive care is all that is available at this time.

Cimetidine in Pregnancy: Apparent Transient Liver Impairment in the Newborn

Cimetidine, a potent H_2 receptor antagonist, recently introduced for the treatment of peptic ulcer and other related disorders, has gained widespread use. Most of the current knowledge of its use and effects is based on adult clinical trials. There is a lack of data on its effects in children and infants and virtually none on the human fetus. Animal studies using radioactive labeled cimetidine at doses of 100 mg/kg indicate that this drug crosses the placental barrier and has thus the potential of producing a systemic effect in utero. Elevated transaminase levels have been reported in adults,[1,2] and cholestatic jaundice has been observed in children.[3] This report concerns the finding of liver impairment in an infant born to a mother receiving cimetidine in the last trimester of her pregnancy.

Report of a Case.—This male patient was born to a 39-year-old, gravida 4, para 2, still-birth 1 whose pregnancy was complicated by an exacerbation of her peptic ulcer disease two months prior to delivery. This was treated initially with a mixture of aluminum hydroxide gel and magnesium hydroxide (Maalox) and with belladonna alkaloids with phenobarbital (Donnatal). One month later, she was hospitalized with a bleeding ulcer and started receiving cimetidine (Tagamet), 300 mg four times a day, and a mixture of aminoacetic acid and calcium carbonate (Titralac), 0.84 g every eight hours. At the time of delivery, the mother was receiving the same cimetidine and aminoacetic acid-calcium carbonate regimen in addition to prenatal vitamins and iron supplementation.

Birth was at 37 weeks of gestation by vaginal delivery (breech with forceps extraction). The infant was meconium-stained and had Apgar scores of 2 and 5 at one and five minutes, respectively. Birth weight was 1,676 g. The child was transported to our hospital because of respiratory distress, but this was of short duration. On admission, the infant appeared small for gestational age, with widely split sutures, and a liver palpable 4 cm below the costal margin; the spleen was not palpable. Initial laboratory findings included bilirubin levels of 3.7 mg/dL (total) and 1.5 mg/dL (direct) at six hours of age. Bilirubin levels increased and peaked at 4 days of life at a level of 10 mg/dL (total) with 4.5 mg/dL (direct). The bilirubin elevations and other abnormal liver tests are recorded in the Table.

Blood group incompatibility and congenital infections were ruled out as possible causes of jaundice. Toxoplasmosis titer was negative, as well as the results of viral titers that are presented in the Table. Hepatitis B surface antigen was nonreactive, and the T_4 level was 8.6 μg/dL. Further workup resulted in an α_1-antitrypsin level of 400 mg/dL, a negative urinary metabolic screening, and a normal upper gastrointestinal study.

The initial clinical course was characterized by feeding intolerance, inadequate weight gain, and persistence of jaundice. At 2½ weeks of age, phenobarbital therapy was started at a dose of 4 mg/kg/day as an attempt to induce hepatic function. As the total bilirubin level decreased to 1.2 mg/dL, the drug's use was discontinued after 31 days. At 25 days of age, the patient was discharged at the request of the family, weighing 2.04 kg. Follow-up visits at 30, 48, and 62 days of age showed a progressive decrease in liver size, gradual clearance of the jaundice, and an appropriate weight gain. A liver biopsy, although scheduled, was deferred owing to the clinical improvement of the liver disease.

Comment.—Cimetidine crosses the

placenta, but its effect on the human fetus and the newborn infant are unknown. In animal studies, no teratologic effects have been identified on the basis of deformities or early development. The effect of cimetidine on the liver has been documented both in animal and clinical studies. Studies in rats and dogs using supratherapeutic dose ranges have demonstrated elevated serum transaminase and alkaline phosphatase levels, with liver biopsy specimens showing centrilobular degenerative changes and inflammatory cell infiltration.[4]

In the early adult human studies, transient elevations in SGOT, SGPT, lactic dehydrogenase, alkaline phosphatase, and bilirubin were recorded and rarely became of any major clinical consequence.[1] Sharpe and Hawkins[2] reported clinically important increases in transaminase levels in four adult patients, two of whom showed mild centrilobular necrosis on liver biopsy specimen. A recent study[3] of children (1 year to 14 years old) treated with cimetidine reported a finding of cholestatic jaundice with elevations of serum bile acids, bilirubin, SGOT, and alkaline phosphatase. The presence of hepatic excretory impairment in our paitent points to a possible contributing effect of cimetidine administration in utero. The progressive elevation in bilirubin from birth to day 4 in our patient may be explained on the basis of removing the placenta as a source of bilirubin elimination.[5,6]

The mechanism by which cimetidine affects hepatic function is unclear. Kinetic studies in man indicate that the drug is primarily excreted by the kidney, 50% to 60% unchanged, and the remainder as conjugates and metabolites, with fecal excretion approximating 10%. The major metabolite is the sulfoxide, accounting for 10% of the urinary excretion.[7] Biliary levels of cimetidine have been reported to be higher than portal or systemic blood levels.[8] This finding sets the potential for a possible interference with hepatic excretory function (eg, hepatic bile acid transport). The immature liver of a fetus and/or premature infant would possibly be more susceptible to a drug causing minor degrees of interference with bile acid transport. The other drugs ingested by the mother have not been associated with liver impairment. The question that surfaces by this case account is whether cimetidine causes hepatic dysfunction in utero and postnatally. This report does no more than suggest a causal relationship, but we believe it may justify the need for carefully monitoring pregnant patients given cimetidine therapy, particularly looking at the outcome of delivery and offspring. Further analysis of cimetidine therapy in pregnancy is warranted to resolve its in utero effect.

Herpes Simplex Infection After Needle Aspiration of a Lymph Node

Primary infection with herpes simplex virus (HSV) occurs often in childhood. The most common manifestation is gingivostomatitis, while keratoconjunctivitis and skin disease are uncommon.[1-3] Few reports of culturally confirmed, localized, posttraumatic herpes simplex infection during childhood, apparently unrelated to autoinoculation, exist in the literature.[3-5] We report a traumatic HSV skin infection occurring three days after needle aspiration of a presumed bacterial cervical adenitis.

Report of a Case.—An 18-month-old, previously healthy boy developed diffuse swelling of the right side of the neck one day before admission. The past medical history included a unilateral otitis media two months prior to admission. He had no history of herpetic infection nor did any members of his immediate family. Physical examination revealed a listless, febrile (39.2 °C) toddler with a firm, tender mass obscuring the angle of the mandible and extending over the sternocleidomastoid muscle. The overlying skin was hot and erythematous. The rest of the physical examination was unremarkable. The WBC count was 19,500/cu mm, with a shift to the left. Blood cultures were sterile. He was initially treated with a cephalosporin, without improvement. On the third day of hospitalization, a needle aspirate from the mass revealed small, Gram-negative rods

Crop of vesicles that appeared at site of cervical lymph node aspiration.

resembling *Haemophilus influenzae*, but the bacterial culture was sterile. He was given ampicillin sodium, and three days later, when the patient was improving, a vesicular eruption was noted at the aspiration site (Figure). Scrapings from the base of the vesicles revealed numerous multinucleated giant cells. Herpes simplex virus was isolated from the vesicle fluid in human embryonic kidney cells. The virus was identified as type 1 by a direct immunofluorescence technique. The adenopathy resolved uneventfully with treatment. The complement fixation (CF) titer to HSV was 1:16, and the indirect hemagglutination titer to type 1 HSV was 1:4,096 one month after infection.

Comment.—The present case represents an unusual example of traumatic herpes infection that may be encountered in clinical practice. Since two thirds of herpetic infections are asymptomatic[3] and a history of previous infection or exposure is often absent, it is difficult to differentiate between primary infection and recurrence. In addition, CF antibody titer to HSV can be low at the initial phase of a recurrence.[3] Without an acute serum specimen or previous history of disease, we were unable to determine if this patient's disease was a primary infection or reactivation of latent virus.

Latent infection can be activated by a variety of factors such as fever, emotional reactions, upper respiratory infection, pneumococcal or meningococcal infection, excessive exposure to sunlight, and local trauma.[2,3,6] Examples of local trauma resulting in disease include herpes labialis after blow-out fractures of the orbit[7]; herpetic whitlow after trauma to fingers[3,8]; cutaneous eruptions after trigeminal nerve rhizotomy,[6] shaving,[3] smallpox vaccination,[5] intramuscular injections,[9] or direct trauma from falling[3]; herpes gladiatorum in wrestlers[2]; and tracheal ulcers after intubation.[10]

The rapid response to ampicillin and the Gram-negative rods seen on Gram's stain suggest a bacterial etiology for the cervical adenitis. However, a herpetic etiology is also possible and could not be excluded with the available information.

Severe Neonatal Chlamydial Pneumonitis

Chlamydia are bacteria-like obligatory intracellular parasites. Although they were considered once to be large viruses, they differ from the viruses in having two nucleic acids and in having a discrete cell wall. They do resemble viruses only in the obligatory intracellular nature of their parasitism.[1,2]

A number of human diseases are caused by *Chlamydia*. Recent studies have shown that chlamydial infection in the newborn is associated with a pneumonia syndrome that is characterized by an afebrile course, chronic diffuse lung involvement, tachypnea, and elevated serum IgG and IgM levels.[3-5]

In the 2-week-old infant with severe pneumonitis who is to be described, *C trachomatis* was isolated from tracheal aspirates as well as from her mother's cervix.

Report of a Case.—A 4,100-g term female infant was born to a 30-year-old mother, after a normal pregnancy, labor, and delivery. There was no maternal history of conjunctivitis, or of respiratory or genital infection during pregnancy. The infant was discharged from the nursery after four days. A day later, the infant was found to have a temperature of 39 °C and, two days later though her temperature had returned to normal she began to feed poorly and a mild cough developed. For the next six days, progressive tachypnea and cyanosis were noted by the parents.

On admission to the pediatric intensive care unit, the infant was cyanotic, with respirations of 120/min and severe chest retractions but she was afebrile. Diffuse crepitations and diminished breath sounds were audible in both lungs. The remainder of the physical examination was unremarkable.

Chest roentgenogram disclosed bilateral diffuse interstitial infiltrates (Fig 1). Laboratory tests included a hemoglobin level of 9.6 g/dL, a WBC count of 14,000/cu mm, with 20% neutrophils, 20% band forms, 50% lymphocytes, 5% monocytes, and 5% eosinophils. There were no findings indicating hemolysis. Blood loss could be attributed to withdrawal of blood for investigations. Serum immunoglobulins were as follows: IgA, 20 mg/dL (normal, 4 to 35); IgM, 280 mg/dL (normal, 20 to 80); IgG, 980 mg/dL (normal, 350 to 1,000). The laboratory values for blood urea, creatinine, calcium, uric acid, and urinalysis were within normal limits. Arterial blood sample on admission showed a pH of 7.23, a $Paco_2$ of 65 mm Hg, and a PaO_2 of 40 mm Hg.

The infant was intubated and mechanically ventilated for the next five days. Subsequently, a gradual improvement in the clinical as well as in the arterial blood gas analysis was noted and the infant was extubated on the sixth hospital day, at which time the chest roentgenogram showed some clearing of both lung fields. The infant was given supplemental oxygen via oxyhood for the next two weeks. A week after extubation, arterial blood sample revealed a pH of 7.38, a $Paco_2$ of 44 mm Hg, and a Pao_2 of 88 mm Hg while on

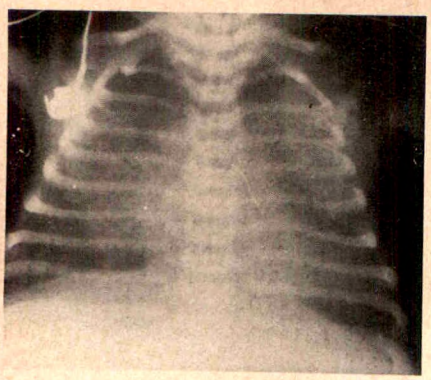

Fig 1.—Chest roentgenogram, obtained on first hospital day, showing severe bilateral interstitial pneumonitis.

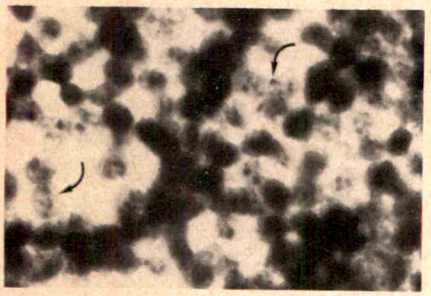

Fig 2.—Two McCoy cell populations are demonstrated (Giemsa stain, ×450). Dark homogenous-appearing cells are unaffected McCoy cells. Light granular-appearing cells contain typical inclusion bodies of *Chlamydia trachomatis* (arrows).

fraction of inspired oxygen of 0.3.

Tracheal aspirates, which were studied for bacteria and viruses (cytomegalovirus, respiratory syncytial virus, rubella, influenza, parainfluenza) were negative. Methenamine silver nitrate stain of the aspirated material for *Pneumocystis carinii* was also negative. Cultures for *C trachomatis* were positive.

No antimicrobial therapy was administered and the patient was discharged on the 21st hospital day after having recovered completely from the pneumonitis. Chest roentgenogram as well as arterial blood gases on the day of discharge were within normal limits.

Patient Sampling and Specimen Processing.—We obtained tracheal aspirates from the patient, under direct laryngoscopy, by a No. 5 F feeding tube. Approximately 0.3 mL were aspirated and then suspended in 3 mL of collecting medium consisting of sucrose-phosphate medium with 5 mγ/mL of streptomycin and 25 units/mL of nystatin. Cultures from the cervical discharge of the infant's mother were obtained under direct vision with a cotton-tipped applicator and were then immersed and wrung out in the collecting medium.

Bacteriologic cultures were processed in the laboratory according to standard procedures for aerobic bacteria. In an attempt to isolate viruses, tracheal aspirates were inoculated onto a primary human kidney (embryo) and African green monkey kidney cell lines and followed up for three weeks. For isolation of *Chlamydia*, cytochalasin B-pretreated McCoy cells were used according to the method of Sompolinsky and Richmond.[6] Isolates that formed iodine-staining cytoplasmatic inclusion bodies were considered to be strains of *C trachomatis*. A two-dimensional immunoelectrophoresis, which was used according to the method of Caldwell et al,[7] also confirmed that the isolates are of the human strain. The cultures were stained by Giemsa for microscopic examination (Fig 2).

Comment.—Interstitial pneumonitis in early infancy is a common clinical problem for which viruses are often incriminated. Beem and Saxon[4] have shown the association between the presence of nasopharyngeal *C trachomatis* and a pneumonia syndrome of infancy. *Chlamydia trachomatis*, the etiologic agent of trachoma,[8] inclusion conjunctivitis,[9] and some of the nongonococcal urethritis,[10] causes pneumonitis in infants that is manifested by nasal obstruction and discharge, staccato cough, tachypnea, and afebrile course, and elevated serum levels of IgG and IgM. Six weeks was the typical age at diagnosis and inclusion conjunctivitis was diagnosed in only 50% of the infants in the patients studied by Beem and Saxon.[4]

Frommell and associates[11] reported a case of *C pneumonitis* in which the patient underwent open lung biopsy, which yielded positive cultures for *Chlamydia* and cytomegalovirus. What is to our knowledge the first pure chlamydial pneumonitis proved by biopsy specimen, of a 5-week-old boy, has been described recently by Arth et al.[12]

Although all previous reports of chlamydial pneumonitis have not been associated with severe morbidity or mortality in infants, our patient was critically ill.

Erythromycin and sulfonamides are currently the most acceptable antimicrobial agents in this pediatric age group.[13] In our case, antimicrobial therapy was not started since the clinical condition, the laboratory findings, and the chest roentgenogram suggested viral pneumonitis. *Chlamydia trachomatis* was isolated on the eighth day of the illness, while the infant was already recovering; hence, specific treatment was not considered essential.

Studies performed by Chandler et al[14,15] and by Shachter and his colleagues,[5] showed that the range of the chlamydial carrier state in pregnant women is between 5% and 13%; thus, a substantial proportion of neonates are at risk. Chandler and associates[14] showed that 50% of the neonates born to women who carry the infection acquired inclusion conjunctivitis. It was also estimated[5] that the incidence of neonatal chlamydial pneumonitis is three to four per 1,000 live births. This relatively high incidence suggests that serious consideration should be given to screening of pregnant women routinely, isolation of *Chlamydia*, and effectively treating them prior to delivery.

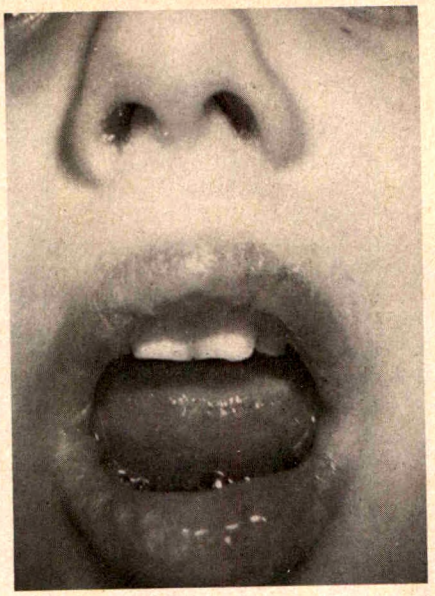
Acute Glossitis and Septicemia Owing to *Haemophilus influenzae* Type B

Acute bacterial glossitis occurs infrequently, judging by the lack of reported cases in the English literature. *Pseudomonas* sp and hemolytic streptococci have been implicated as causative agents of suppurative parenchymatous glossitis.[1] Two cases of acute glossitis owing to *Haemophilus influenzae* type B have been reported, both of them within the past three years.[2,3] We report another case of *H influenzae* type B glossitis to further promote awareness and recognition of this disease.

Report of a Case.—This 4-year-old boy complained of a swollen and painful tongue. He was well until the evening prior to consultation when he complained of a vague discomfort of the tongue. Inspection of the child's mouth by his father did not yield any unusual findings. The child's buccal cavity was sprayed with a mouthwash and he was put to bed. Early the next morning, the patient woke up complaining of increased lingual pain. Swallowing was difficult and the child was drooling. Swelling of the tongue was noted by his parents. The swelling increased during the next three hours, so the child was taken to the emergency room.

On arrival, he appeared moderately ill, uncomfortable, and anxious. He had a temperature of 40.3 °C. He was drooling and refused to talk. His mouth was partially open. His tongue was erythematous, swollen, and tender, almost filling the anterior oral cavity (Figure). The swelling was diffuse but was most prominent in the anterior portion. There was no evidence of injury to the tongue. No associated cervical adenitis was noted. The rest of the physical examination was unremarkable.

Roentgenograms of the soft tissues of the neck showed a large tongue; otherwise, the upper airway showed no abnormalities. The chest roentgenogram was clear. He had a WBC count of 8,900/cu mm, with 80% neutrophils, 9% band forms, and 11% lymphocytes. A diagnosis of acute glossitis was made. A blood culture was done, and the child was given oral oxacillin sodium after an initial intramuscular dose. He was discharged to go home, with instruction to return in eight hours for reevaluation.



Partially open mouth, swollen tongue, and drooling evident on examination.

On return, the oral findings were unchanged. The patient and his parents, however, claimed that he was better. His temperature was 38.5 °C. Continued management of his condition on an outpatient basis was advised. About 24 hours after the initial examination, β-lactamase-negative *H influenzae* type B was isolated from the blood. The patient was recalled and admitted to the hospital for intravenous (IV) ampicillin sodium therapy. He was afebrile and had less pain of the tongue. A repeated blood culture prior to ampicillin therapy also had β-lactamase-negative *H influenzae* type B growth.

One day after starting ampicillin therapy, the patient was afebrile, happy, conversant, and able to tolerate solid food. The lingual swelling had greatly regressed. After completing three days of IV treatment, the patient was sent home with instructions to take oral ampicillin trihydrate for seven more days. The tongue appeared normal. Reevaluation of the patient's condition one month after discharge showed complete resolution of the glossitis.

Comment.—Cellulitis is the most common form of soft-tissue infection caused by *H influenzae* type B. About two thirds of the cases involve the cheeks; approximately 80% are septicemic.[4,5] In 1976, Granoff and Nankervis[2] observed a child, with *H influenzae* type B facial cellulitis, who had diffuse swelling of the tongue and uvula. Subsequently, Edwards and Reynolds[3] described a child with bacteremia owing to *H influenzae* type B in whom swelling of the tongue was the distinctive initial manifestation. Our observation of yet another case of acute swelling of the tongue and septicemia owing to *H influenzae* type B suggests that this organism has an important role in the causation of acute glossitis.

The initial management of our patient's condition reflects the dearth of epidemiologic data on acute bacterial glossitis. The choice of oxacillin for the initial therapy was based on the presumption that the most likely etiologic agent was a Gram-positive microorganism, possibly *Staphylococcus aureus*, or one of the penicillin-sensitive bacteria that comprise the normal oral flora. After the beginning of oxacillin therapy, an apparent clinical improvement occurred in spite of a persistent *H influenzae* bacteremia. This falsely reassuring clinical response could conceivably lead to a delay in starting specific antibiotic therapy and thus could promote metastatic seeding of the meninges, the joints, or other organs. Our experience, as well as that of others, dictate that an *H influenzae* type B infection should be considered in a febrile child who has acute swelling of the tongue. The initial antibiotic therapy of acute glossitis should include drugs effective against *H influenzae*.

Books

Prenatal Diagnosis of Genetic Disease, by D. C. Siggers, $9, 69 pp, 17 illus, London, Blackwell Scientific Publications, 1978.

This is a thin paperback with a total of 69 pages, of which 44 are text and the remainder are taken up by a list of genetic centers in Britain and the index. As the author states in his preface, the book is intended for postgraduate students in obstetrics, pediatrics, and general practice as well as for medical students, midwives, and pediatric nurses. It is oriented for use in the United Kingdom, but may be of interest to the aforementioned groups elsewhere. It would be particularly useful for the obstetrician who wants a succinct, clearly written review of current aspects of that nagging problem of prenatal diagnosis. The illustrations are good, especially the diagram that shows the risks of trisomy 21 at each year of maternal age from 34 to 41 with the use of Hook's up-to-date data. It is too elementary for medical students, who will have had much more detail in their courses in human genetics.

In addition, Dr Siggers' book provides us with a "slice of life," a snapshot of the situation in prenatal diagnosis in the late 1970s with laboratories for prenatal diagnosis desperately trying to accommodate increasing service loads. The first diagram in the book graphically illustrates the 150-fold increase in service load between 1971 and 1977 at a British cytogenetics unit.

It is unfortunate that the book is quite expensive. Perhaps in a second edition the lists of genetic centers could be left out, since these are already available in the National Foundation's international directory.

Surgical Management of Juvenile Chronic Polyarthritis, by G. P. Arden, 281 pp, $32.25, New York, Grune & Stratton Inc, 1979.

This book comes from the group associated with the Juvenile Rheumatism Unit at Taplow, Buckinghamshire, England. This unit, founded by Prof E. G. L. Bywaters and soon joined by Barbara Ansell, was a major source of training for many pediatric rheumatologists around the world, and provided care for hundreds of children with arthritis.

The first chapter by Ansell presents a brief and excellent overview of juvenile rheumatoid arthritis (JRA), including the recent attempts in the United States, England, and Europe to reclassify these diseases as they appear in children. The development of subclassification in JRA is of value because with it one would be able to better define the course and progression of the disease as it occurs in an individual child. Unfortunately, this theme was not carried out fully in the chapters on surgery. For example, in the chapter on synovectomy of the knee, there was an initial description of the patients undergoing synovectomy based on whether or not they had sero positive and sero negative JRA of polyarticular and pauciarticular types. But then the author used the term *generalized,* a classification not used initially. He also describes his results in patients with sero positive JRA age 16 to 21 years. However, JRA has been defined as occurring in patients younger than 16 years. Occasionally, the captions under the generally good illustrations do not provide enough information, such as the age or sero positivity of the patient involved.

I cannot agree with Professor Bywaters when, at one point in an otherwise well-illustrated chapter on the pathology of JRA, he states that "in monarticular arthritis . . . a synovial biopsy is almost always necessary, certainly after one month's duration." This indication is not recognized by most pediatric rheumatologists in the United States and I doubt the necessity for such frequency. We are dealing with a condition that involves less than 10% of all the children we see in the usual pediatric arthritis clinic; in half of them, it will resolve within five years (frequently within one year). Careful clinical follow-up should precede any requirements for biopsy. Many other diseases with monarticular onset can be generally eliminated because of their rarity, geographic area, and by clinical and laboratory studies. These, as presented by Professor Bywaters, are sarcoidosis, thorn synovitis, fungal lesions, tuberculosis, other infectious arthritis, pigmented villonodular synovitis, scleroderma, and lupus erythematosus. These zebras may be present, but the pounding hoofbeats are 99% monarticular JRA.

The description by G. P. Arden of total joint replacement is a fascinating assessment of a long and careful experience in these children. This chapter should be of particular interest to both the rheumatologist taking care of these children and to the orthopedist who will be called in to do these procedures. There is good practical information for both.

Harrison's chapter on hand deformities and their correction by splinting and surgery with good descriptions of the operative and nonoperative techniques for maintaining and restoring hand function is of value to the reader. A more detailed description of rehabilitation techniques and the prosthetic devices used for correction and prevention of deformities is presented by Ansell. The disturbing frequency of loss of vision due to the chronic iridocyclitis seen most frequently in those children with pauciarticular disease is discussed in detail by Smiley and Kanski. Their excellent results with the new technique of lensectomy are described in detail and represent an exciting development in a condition heretofore difficult to treat.

Professor Bywaters has provided us not only with the general pathology of juvenile arthritis and some of its mimics but also, with Mr Arden, gives a detailed description of tissue reaction. Most of this chapter is devoted to a description of the failures of prosthesis from the mechanical point of view as well as from infection and allergic and toxic reactions to the materials used.

This slim volume contains a wealth of information of value to the pediatric rheumatologist, orthopedist, ophthalmologist, and pathologist involved in the care of children with juvenile arthritis. It does not provide enough information on therapy for the pediatrician who might have one or two patients with JRA in his practice.

Letters to the Editor

Marden-Walker Syndrome

Sir.—The interesting article entitled "Zollinger-Ellison Syndrome With Marden-Walker Syndrome" (JOURNAL 133:735-738, 1979) states that this is the fifth reported case of the Marden-Walker syndrome. However, it is the sixth, as in 1971 we published a case.[1]

Idiopathic Thrombocytopenic Purpura (ITP)

Sir.—I read with interest the article by Movassaghi et al entitled "Antiplatelet Antibodies in Childhood Idiopathic Thrombocytopenic Purpura" (JOURNAL 133:257-259, 1979). However, I cannot agree with their conclusion that platelet antibody usually disappears with recovery from thrombocytopenia in childhood ITP. We have already shown in three chronic and five acute cases of childhood ITP that have been in remission for up to six years that mean platelet survival is shorter with platelet opsonization in five cases (in whom it could be determined).[1,2]

The study has been extended to include 14 children with ITP (six chronic and eight acute) in remission, and again, severe reduction in platelet survival (mean, 4.0 days, which is shorter than in previous reports[1,2]) with platelet opsonization was shown in every case. The antiplatelet antibodies shown by the Handin and Stossel method[3] related to acute phase and remission of 49 childhood ITP cases, and their specificity to IgG will be reported.[4]

Our conclusions from these studies are as follows: antiplatelet antibodies are not only present in the acute phase, but can also be shown in remission in acute and in chronic childhood ITP cases. These antibodies are only in the IgG fraction, as in adult ITP, and are specific for platelets. The pathogenesis of ITP in childhood is not different from that in adult ITP. Since the platelet antibodies do not disappear from the serum during the remission stage, the shorter platelet survival is easily understood in acute and chronic ITP in remission.

Diabetes Mellitus, Hashimoto's Thyroiditis, and Juvenile Rheumatoid Arthritis

Sir.—We read with interest the report of Collen et al that detailed a case of primary ovarian failure, juvenile rheumatoid arthritis (JRA), and vitiligo (JOURNAL 133:598-600, 1979). We, too, have studied a patient with JRA and an autoimmune polyendocrinopathy.

Report of a Case.—A 15-year-old girl with chronic eczema had insulin-dependent diabetes mellitus (DM) at age 6 years, euthyroid goiter at age 9 years, and debilitating polyarticular JRA with subcutaneous nodules at age 12 years. There was a family history of DM and goiter in the mother and the maternal relatives. After therapy with thyroid and gold, the goiter regressed and the arthritis improved.

Laboratory tests performed at age 13 years showed the following levels: fasting blood glucose, 208 mg/dL; urinalysis, 4 + for glucose, negative acetone, and protein; sedimentation rate, 33 mm/min; VDRL, negative; antinuclear antibody, 1:32, 768; rheumatoid factor, 1:640; antiextractable nuclear antigen, negative; anti-DNA, 27% (normal, < 30%); serum DNA, negative; C_3, 240 mg/dL (normal, 85 to 225 mg/dL); C_4, 57 mg/dL (normal, 20 to 40 mg/dL); total protein, 8.4 g/dL; albumin/globulin ratio, 0.9; γ globulin, 34.2%; IgG, 2,130 μg/dL (normal, 900 to 1,500 μg/dL); IgM, 126 μg/dL (normal, 70 to 280 μg/dL); IgA, 110 μg/dL (normal, 90 to 450 μg/dL); roentgenograms of wrists, bony changes compatible with JRA; tetraiodothyronine, 10.0 μg/dL; antithyroglobulin antibody, 1:68, antimicrosomal antibody, 1:7,000; cortisol baseline, 7.4 μg/dL; cortisol postadrenocorticotropic hormone stimulation, 27.7 μg/dL; antiadrenal antibody, negative; serum B_{12} and peripheral smear, normal; antiparietal cell antibody, negative; and, histocompatibility antigen typing, A28, A9, B27, B7, Cw2.

Comment.—Juvenile DM is now believed to have an autoimmune basis.[1] Thus, our patient displays evidence of three diseases of autoimmune origin: juvenile DM, Hashimoto's thyroiditis, and JRA. To our knowledge, she is the second reported patient with this combination of diseases; a previous case was presented as part of a clinicopathologic conference in 1968.[2] The diagnosis of JRA is supported in our patient by the clinical, radiologic, and laboratory findings. Histocompatibility antigen typing showed B27, but not B8. Other diseases of autoimmune origin were ruled out.

Clinical and serologic associations between juvenile DM and thyroid disorders, including Hashimoto's thyroiditis, have been established.[3] An

association between adult rheumatoid arthritis (but not JRA) and Hashimoto's thyroiditis is also known.[4] To date, there has been no established association between juvenile DM and JRA, although reports of juvenile DM concommitant with other connective tissue diseases have been noted.[5]

As Collen et al remarked in regard to their patient, we believe that our patient displays a widespread autoimmune disturbance of which the three diseases are individual manifestations. The eczema may be a fourth manifestation.[6] We believe that the association of JRA and the autoimmune endocrinopathies is not a fortuitous finding, and we expect that additional reports of such cases will be forthcoming.

Hearing Loss and Learning Disability

Sir.—In a recent JOURNAL (132:1100-1104, 1978), Zinkus et al reported that children who have had a history of severe, chronic otitis media suffer later from developmental and learning problems. They conclude that hearing loss is the culprit.

Although they refer to an earlier article by Kaplan et al,[1] the authors fail to note that those investigators found no relationship between the degree of otitis media–caused hearing loss and learning problems. Kaplan et al found only the same correspondence between chronic otitis media and learning disorders that Zinkus found.

There is no evidence that the mild hearing loss associated with otitis media causes poor learning, nor is it known what causes the relationship between otitis media and learning disorder. I have suggested elsewhere[2] that a third factor, related to the predisposition to learning disability, may be responsible for the occurrence of chronic otitis media as well.

LEONARD HERSHER, PhD
Department of Pediatrics
Upstate Medical Center
750 E Adams St
Syracuse, NY 13210

1. Kaplan GJ, Fleshman JK, Bender TR, et al: Long-term effect of otitis media. *Pediatrics* 52:577-585, 1973.

2. Hersher L: Minimal brain dysfunction and otitis media. *Percept Mot Skills* 47:723-726, 1978.

In Reply.—To conceptualize the results of our investigations as a statement that otitis media-related hearing loss causes poor learning is oversimplistic and reflects a lack of understanding. We have suggested that transient hearing loss and distortion of auditory signals during the early language-formative years results in deficiencies in language development. One aspect of receptive language, auditory processing, may be compromised, with effects observed in academic areas. By disrupting the normal sequence of language development, the repeated episodes of otitis media-induced hearing loss have an indirect effect on subsequent academic performance.

A considerable body of evidence exists that confirms that hearing loss, associated with early chronic otitis media, compromises a child's language development.[1] The effects of hearing loss can be observed even during the prelinguistic babbling phases of early infancy.[2] Additionally, otitis media-induced hearing loss has been associated with deficiencies in receptive language, expressive language, and verbal intelligence.[3] There can be little doubt that the deficiencies in language development seen in young children with chronic otitis media result to a large degree from impaired auditory acuity.

We are further concerned with otitis media-produced hearing loss in infants and young children. It seems pretentious to assume that any hearing loss during this period of language development is "mild" in relation to the same degree of loss in adults. As Howie[4] has suggested, hearing loss in infancy and early childhood is more critical since the children have "little previous auditory experience." In this case, "mild" loss may not mean mild effect. Unfortunately, the fragile sequence of language development does not adhere to the arbitrary scaling of severity of hearing loss. Deprivation of high quality auditory input during the first two to three years of life may result from as little as 15 dB threshold.[1]

We have attempted to avoid nebulous and often ambiguous terms, such as learning disability or learning disorder. Instead, we have focused on those aspects of information processing that are most closely related to the auditory mechanism, ie, auditory processing. Our subjects with severe chronic otitis media consistently evidenced delays in their ability to use the full receptive capabilities of the auditory mechanism. Their ability to process auditory information was deficient, a fact that was evidenced in delayed language and, later, in disrupted auditory processing skills. Deficiencies in auditory processing are known to disrupt reading and spelling skills, as was found in our study.

We have offered this hypothesis as a beginning point for further testing, hopefully through future longitudinal prospective studies. In response to Herscher's statement, I would agree that other variables may predispose some children to be high risk candidates for more severe sequelae related to their otitis media. However, we did not imply that hearing loss associated with otitis media *causes* poor learning. Rather, there are language-related sequelae that reduce the ability of the child to process auditory information, and these effects may be seen even after the ear disease has been resolved.

A newly developed oral antibiotic

Ceclor® cefaclor

Consider the changing bacterial

Increasing incidence of otitis media caused by H. influenzae

Reports from many areas of the country show that the bacterial pattern seen in otitis media is changing. Published studies suggest that the incidence of otitis media caused by *H. influenzae* is increasing.[1,2]

In fact, the American Academy of Pediatrics' Committee on Infectious Diseases reports that relapses of otitis media have been more common with *H. influenzae* than with other organisms.[3]

H. influenzae resistance is a growing problem

Percentage of Ampicillin-Resistant *H. influenzae* Isolates*

	1975	1976	1977
Boston[4]	5.3%	10.2%	15.6%
Fresno[5]	—	—	4.8
Huntsville[4]	1.4	2.8	13.6
Washington, D.C.[6]	1.6	18	35
Oklahoma City[7]	—	—	22

*Isolates obtained from a variety of body fluids (middle-ear exudate, blood, etc.).

Recommendations regarding treatment of otitis media caused by H. influenzae

The American Academy of Pediatrics, in its recommendations for the treatment of otitis media, reports that *H. influenzae* is often the suspected pathogen in children less than eight years of age. They further report that ampicillin-resistant strains of *H. influenzae* have been isolated. The physician should therefore consider ampicillin resistance in the child with acute otitis media, particularly one who does not show clinical improvement after 48 to 72 hours of ampicillin therapy.[8]

Investigators have suggested a need for alternative antimicrobials in the treatment of otitis media caused by ampicillin-resistant *H. influenzae*.[9,10]

Ceclor® (cefaclor) is effective in the treatment of acute otitis media due to susceptible strains of these microorganisms:

- *S. pneumoniae*
- *H. influenzae* (including beta-lactamase-producing ampicillin-resistant strains)
- Staphylococci (including coagulase-positive, coagulase-negative, and penicillinase-producing strains)
- *S. pyogenes* (group A beta-hemolytic streptococci)

In studies of 246 patients with otitis media, Ceclor demonstrated a 93 percent clinical and bacteriologic success rate (see accompanying chart).[11]

Clinical and Bacteriologic Responses by Pathogen in 246 Infants and Children with Otitis Media[11]

		Satisfactory Responses	
Pathogen	Number of Patients	Clinical (Symptomatic)	Bacteriologic
S. pneumoniae	127	121	121
S. pyogenes	11	11	11
Staphylococcus aureus	21	18	19
H. influenzae	74	67	66
Multiple organisms	13	12	12
Totals	246	229 (93%)	229 (93%)

See the following page for criteria for diagnosis and response.

pattern of acute otitis media*

Good taste and t i d administration may aid patient compliance

Ceclor may be administered t i d. The pleasant-tasting oral suspensions encourage patient cooperation:

125 mg/5 ml, strawberry flavor
250 mg/5 ml, grape flavor

Criteria for diagnosis and response

Diagnosis:
Diagnosis of otitis media was confirmed in all patients by culture of middle-ear aspirate or exudate within 24 hours after the start of therapy. Exudate was acceptable as a culture source for only pneumococci, *H. influenzae*, and group A streptococci. Additional specimens for culture were obtained during and after therapy as deemed necessary by the clinician. The bacteriologic response was based on results during the ten to 16-day posttherapy follow-up period.

Clinical (symptomatic) response:
Satisfactory = disappearance of or improvement in signs and symptoms of the principal infection, with or without recurrence of signs or symptoms during the posttherapy follow-up period.

Unsatisfactory = no improvement in signs and symptoms at the end of therapy.

Bacteriologic response:
Cure = pathogen(s) eliminated or reduced to insignificant numbers during therapy or elimination of the original pathogen during therapy, followed by a culture positive for a new pathogen (reinfection) either during therapy or during the posttherapy follow-up period.

Failure = failure of the treatment to eradicate the pathogen(s) or initial eradication of the pathogen(s), followed by relapse with the same pathogen during therapy or during the posttherapy follow-up period.

Ceclor is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

*Due to susceptible strains of *S. pneumoniae*, *H. influenzae*, staphylococci, and *S. pyogenes*.

Ceclor® (cefaclor) is also indicated for these other common infections

Clinical trials have demonstrated the effectiveness of Ceclor against the following common infections when caused by susceptible strains of the designated microorganisms:

Lower respiratory infections
including pneumonia caused by *S. pneumoniae*, *H. influenzae*, and *S. pyogenes* (group A beta-hemolytic streptococci)

Upper respiratory infections
including pharyngitis and tonsillitis caused by *S. pyogenes* (group A beta-hemolytic streptococci)

Urinary tract infections
including pyelonephritis and cystitis caused by *Escherichia coli*, *Proteus mirabilis*, *Klebsiella* species, and coagulase-negative staphylococci

Skin and skin-structure infections
caused by *S. aureus* and *S. pyogenes* (group A beta-hemolytic streptococci)

Note: Penicillin is the usual drug of choice in the treatment and prevention of streptococcal infections, including the prophylaxis of rheumatic fever. See summary of prescribing information.

See the following page for summary of prescribing information.

000099

•A newly developed oral antibiotic

Ceclor® cefaclor

Pediatric Dosage			
Mild to Moderate Infections (20 mg/kg/day)			
125 mg (½ tsp t i d)		**125 mg** (1 tsp t i d)	**250 mg** (1 tsp t i d)
0-20 lb 0-9 kg		20-40 lb 9-18 kg	40-55 lb 18-25 kg
More Serious Infections and Otitis Media* (40 mg/kg/day)			
125 mg (½ tsp t i d)	**125 mg** (1 tsp t i d)	**250 mg** (1 tsp t i d)	**250 mg** (1 gm in 3 divided doses)
0-10 lb 0-4.5 kg	10-20 lb 4.5-9 kg	20-40 lb 9-18 kg	40-55 lb 18-25 kg

125 mg, Strawberry 250 mg, Grape

The usual recommended daily dosage for children is 20 mg/kg/day in divided doses every eight hours.

In more serious infections, otitis media,* and infections caused by less susceptible organisms, 40 mg/kg/day are recommended, with a maximum dosage of 1 gm per day.

Safety for use in infants less than one month of age has not been established.

*Due to susceptible strains of *S. pneumoniae, H. influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci).

Ceclor® (cefaclor)

Brief Summary. Consult the package literature for prescribing information.

Indications and Usage: Ceclor is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms:

Otitis media caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci)

Lower respiratory infections, including pneumonia caused by *S. pneumoniae (D. pneumoniae), H. influenzae,* and *S. pyogenes* (group A beta-hemolytic streptococci)

Upper respiratory infections, including pharyngitis and tonsillitis caused by *S. pyogenes* (group A beta-hemolytic streptococci)

Note: Penicillin is the usual drug of choice in the treatment and prevention of streptococcal infections, including the prophylaxis of rheumatic fever. Cefaclor is generally effective in the eradication of streptococci from the nasopharynx; however, substantial data establishing the efficacy of cefaclor in the subsequent prevention of rheumatic fever are not available at present.

Urinary tract infections, including pyelonephritis and cystitis caused by *Escherichia coli, Proteus mirabilis, Klebsiella* species, and coagulase-negative staphylococci

Skin and skin-structure infections caused by *Staphylococcus aureus* and *S. pyogenes* (group A beta-hemolytic streptococci)

Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor.

Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PENICILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS TO BOTH DRUG CLASSES (INCLUDING ANAPHYLAXIS AFTER PARENTERAL USE).

Antibiotics, including Ceclor® (cefaclor, Lilly), should be administered cautiously to any patient who has demonstrated some form of allergy, particularly to drugs.

Precautions: If an allergic reaction to cefaclor occurs, the drug should be discontinued, and, if necessary, the patient should be treated with appropriate agents, e.g., pressor amines, antihistamines, or corticosteroids.

Prolonged use of cefaclor may result in the overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Positive direct Coombs tests have been reported during treatment with the cephalosporin antibiotics. In hematologic studies or in transfusion cross-matching procedures when antiglobulin tests are performed on the minor side or in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it should be recognized that a positive Coombs test may be due to the drug.

Ceclor should be administered with caution in the presence of markedly impaired renal function. Under such a condition, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended.

Usage in Pregnancy—Although no teratogenic or antifertility effects were seen in reproduction studies in mice and rats receiving up to 12 times the maximum human dose or in ferrets given three times the maximum human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

Usage in Infancy—Safety of this product for use in infants less than one month of age has not been established.

Adverse Reactions: In clinical studies in 1493 patients, adverse effects considered related to cefaclor therapy were uncommon and are listed below:

Gastrointestinal symptoms occurred in about 2.5 percent of patients and included diarrhea (1 in 70) and nausea and vomiting (1 in 90).

Hypersensitivity reactions were reported in about 1.5 percent of patients and included morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs tests each occurred in less than 1 in 200 patients.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain—Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic—Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic—Transient fluctuations in leukocyte count, predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal—Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

Administration and Dosage:

Ceclor® (cefaclor, Lilly) is administered orally.

Adults—The usual adult dosage is 250 mg every eight hours. For more severe infections (such as pneumonia) or those caused by less susceptible organisms, doses may be doubled. Doses of 4 gm per day have been administered safely to normal subjects for 28 days, but the total daily dosage should not exceed this amount.

Children—The usual recommended daily dosage for children is 20 mg/kg/day in divided doses every eight hours, as indicated:

Child's Weight	Ceclor Suspension 125 mg/5 ml	Ceclor Suspension 250 mg/5 ml
9 kg	1/2 tsp t i d	
18 kg	1 tsp t i d	1/2 tsp t i d

In more serious infections, otitis media, and infections caused by less susceptible organisms, 40 mg/kg/day are recommended, with a maximum dosage of 1 gm per day.

Ceclor may be administered in the presence of impaired renal function. Under such a condition, the dosage usually is unchanged (see Precautions).

In the treatment of beta-hemolytic streptococcal infections, a therapeutic dosage of Ceclor should be administered for at least ten days. [070379]

Have you ruled out cow-milk sensitivity?

The physical symptoms are many and varied: diarrhea, colic, eczema, asthma, vomiting, bronchitis, rhinitis. They can be coupled with behavioral symptoms: repeated refusal of the nursing bottle . . . general fussiness.[1-3]

Alone or together, the manifestations of milk sensitivity are an unnecessary burden for the infant . . . and parents. More important, if unchecked the allergic syndromes can lead to failure to thrive and other serious health problems.[4]

With Isomil® Soy Protein Formula you can avoid the symptoms of milk sensitivity and help confirm your initial diagnosis.

Moreover, Isomil promotes normal growth.[2,5] It looks like milk, it pours like milk and has a pleasant aroma, which help insure acceptability. Unlike milk, Isomil is lactose free. It avoids the possibility of prolonged or recurring diarrhea caused by lactose intolerance.

Consider the possibility of milk sensitivity when associated symptoms are presented. "A high index of suspicion" is essential to its prompt detection.[2,6]

In pediatric infections

Septra®

Each teaspoonful (5 ml) contains:
40 mg trimethoprim and 200 mg sulfamethoxazole

Suspension B.I.D.

Acute
Otitis
Media

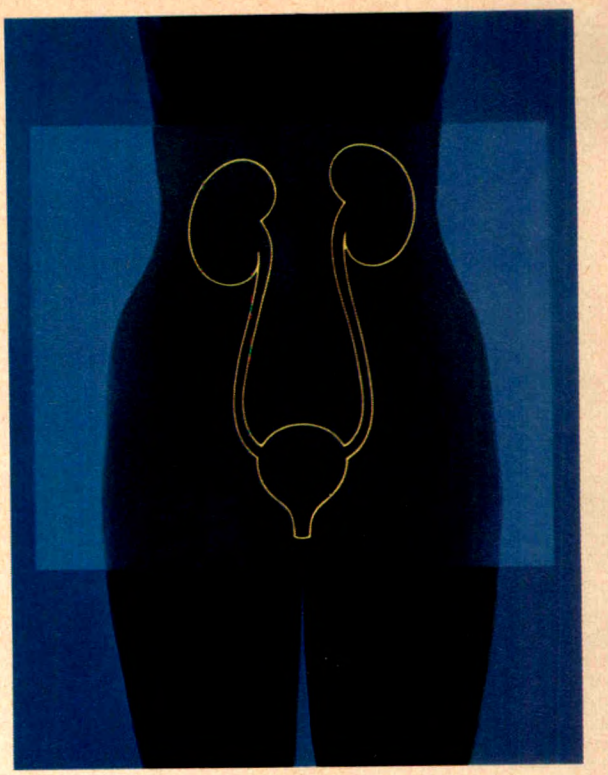
where the action is.

In acute otitis media

- Septra Suspension provides effective antibacterial action against susceptible strains of H influenzae and S pneumoniae (D pneumoniae), the pathogens most likely to cause acute otitis media in children.

Septra Suspension is useful in many patients, but especially in those with penicillin allergy or with infections caused by ampicillin-resistant H influenzae. Limited clinical data are presently available on the effectiveness of treatment of acute otitis media with Septra when the infection is due to H influenzae resistant to ampicillin. However, in vitro data is highly favorable; when over 200 strains of ampicillin-resistant H influenzae were tested, all proved susceptible to TMP/SMX.*

And unlike most other antibacterials for the treatment of acute otitis media, Septra Suspension is administered on a convenient b.i.d. dosage schedule. The cherry-flavored suspension is well accepted by children.



In recurrent urinary tract infections

Septra Suspension provides effective antibacterial action in urine and blood against susceptible strains of E coli, Klebsiella-Enterobacter and Proteus. Whether the infection centers in the kidneys or bladder, Septra Suspension maintains effective levels at the site of the infection with just two doses a day.

Adequate fluid intake should be maintained and frequent urinalyses with careful microscopic examination performed during Septra therapy. Septra is contraindicated in infants under two months of age.

*In vitro data do not necessarily correlate with clinical results. Data on file, Burroughs Wellcome Co.
NOTE: Septra should not be used in the treatment of streptococcal pharyngitis.

Please see prescribing information on next page.

Septra® Suspension B.I.D.

Each teaspoonful (5 ml) contains: 40 mg trimethoprim and 200 mg sulfamethoxazole

Septra® DS B.I.D.

Each tablet contains: 160 mg trimethoprim and 800 mg sulfamethoxazole

Septra® DS Tablets Double Strength
Septra® Tablets
Septra® Suspension

INDICATIONS AND USAGE:
URINARY TRACT INFECTIONS: **For the treatment of urinary tract infections due to susceptible strains of the following organisms:** *Escherichia coli, Klebsiella-Enterobacter, Proteus mirabilis, Proteus vulgaris, Proteus morganii.* **It is recommended that initial episodes of uncomplicated urinary tract infections be treated with a single effective antibacterial agent rather than the combination.**

NOTE: Currently, the increasing frequency of resistant organisms is a limitation of the usefulness of all antibacterial agents, especially in the treatment of these urinary tract infections.

ACUTE OTITIS MEDIA: **For the treatment of acute otitis media in children due to susceptible strains of** *Haemophilus influenzae* **or** *Streptococcus pneumoniae* **when in the judgment of the physician Septra offers some advantage over the use of other antimicrobial agents. Limited clinical information is presently available on the effectiveness of treatment of otitis media with Septra when the infection is due to** *Haemophilus influenzae* **resistant to ampicillin. To date, there are limited data on the safety of repeated use of Septra in children under two years of age. Septra is not indicated for prophylactic or prolonged administration in otitis media at any age.**

SHIGELLOSIS: **For the treatment of enteritis caused by susceptible strains of** *Shigella flexneri* **and** *Shigella sonnei* **when antibacterial therapy is indicated.**

PNEUMOCYSTIS CARINII **PNEUMONITIS: For the treatment of documented** *Pneumocystis carinii* **pneumonitis. To date, this drug has been tested only in patients 9 months to 16 years of age who were immunosuppressed by cancer therapy.**

CONTRAINDICATIONS: Hypersensitivity to trimethoprim or sulfonamides. Pregnancy and during the nursing period. Infants less than two months of age.

WARNINGS: SEPTRA SHOULD NOT BE USED IN THE TREATMENT OF STREPTOCOCCAL PHARYNGITIS.

Clinical studies have documented that patients with Group A β-hemolytic streptococcal tonsillopharyngitis have a greater incidence of bacteriologic failure when treated with Septra than do those patients treated with penicillin as evidenced by failure to eradicate this organism from the tonsillopharyngeal area.

Deaths associated with administration of sulfonamides have been reported from hypersensitivity reactions, agranulocytosis, aplastic anemia and other blood dyscrasias. Experience with trimethoprim alone is much more limited, but occasional interference with hematopoiesis has been reported as well as an increased incidence of thrombopenia with purpura in elderly patients on certain diuretics, primarily thiazides.

Sore throat, fever, pallor, purpura or jaundice may be early signs of serious blood disorders. Frequent CBCs are recommended; therapy should be discontinued if a significant reduction in the count of any formed blood element is noted.

PRECAUTIONS: Use with caution in patients with impaired renal or hepatic function, possible folate deficiency, severe allergy or bronchial asthma. In glucose-6-phosphate dehydrogenase-deficient individuals, hemolysis may occur (frequently dose-related). During therapy, maintain adequate fluid intake and perform frequent urinalyses with careful microscopic examination and renal function tests, particularly where there is impaired renal function.

Since Septra may prolong prothrombin time in patients on warfarin, coagulation time should be reassessed when Septra is given.

ADVERSE REACTIONS: All major reactions to sulfonamides and trimethoprim are included, even if not reported with Septra. *Blood Dyscrasias:* Agranulocytosis, aplastic anemia, megaloblastic anemia, thrombopenia, leukopenia, hemolytic anemia, purpura, hypoprothrombinemia and methemoglobinemia. *Allergic Reactions:* Erythema multiforme, Stevens-Johnson syndrome, generalized skin eruptions, epidermal necrolysis, urticaria, serum sickness, pruritus, exfoliative dermatitis, anaphylactoid reactions, periorbital edema, conjunctival and scleral injection, photosensitization, arthralgia and allergic myocarditis. *Gastrointestinal Reactions:* Glossitis, stomatitis, nausea, emesis, abdominal pains, hepatitis, diarrhea and pancreatitis. *C.N.S. Reactions:* Headache, peripheral neuritis, mental depression, convulsions, ataxia, hallucinations, tinnitus, vertigo, insomnia, apathy, fatigue, muscle weakness and nervousness. *Miscellaneous Reactions:* Drug fever, chills, and toxic nephrosis with oliguria and anuria. Periarteritis nodosa and L. E. phenomenon have occurred.

Due to certain chemical similarities to some goitrogens, diuretics (acetazolamide and the thiazides) and oral hypoglycemic agents, sulfonamides have caused rare instances of goiter production, diuresis and hypoglycemia; cross-sensitivity may exist with these agents. In rats, long-term administration of sulfonamides has produced thyroid malignancies.

DOSAGE AND ADMINISTRATION: Not recommended for use in infants less than two months of age.

URINARY TRACT INFECTIONS AND SHIGELLOSIS IN ADULTS AND CHILDREN AND ACUTE OTITIS MEDIA IN CHILDREN:

Adults: The usual adult dosage for the treatment of urinary tract infections is two tablets or four teaspoonfuls (20 ml) every 12 hours for 10 to 14 days. An identical daily dosage is used for 5 days in the treatment of shigellosis.

Children: The recommended dose for children with urinary tract infections or acute otitis media is 8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole per 24 hours, given in two divided doses every 12 hours for 10 days. An identical daily dosage is used for 5 days in the treatment of shigellosis. The following table is a guideline for the attainment of this dosage using Septra Tablets or Suspension.

Children: Two months of age or older:

Weight		Dose —every 12 hours	
lb	kg	Teaspoonfuls	Tablets
22	10	1 (5 ml)	½
44	20	2 (10 ml)	1
66	30	3 (15 ml)	1½
88	40	4 (20 ml)	2 (or 1 DS tablet)

For patients with renal impairment:

Creatinine Clearance (ml/min)	Recommended Dosage Regimen
Above 30	Usual Standard Regimen
15-30	Half of the usual dosage regimen
Below 15	Use Not Recommended

PNEUMOCYSTIS CARINII **PNEUMONITIS:**
The recommended dosage for patients with documented *Pneumocystis carinii* pneumonitis is 20 mg/kg trimethoprim and 100 mg/kg sulfamethoxazole per 24 hours given in equally divided doses every 6 hours for 14 days. The following table is a guideline for the attainment of this dosage in children.

Weight		Dose —every 6 hours	
lb	kg	Teaspoonfuls	Tablets
18	8	1 (5 ml)	½
35	16	2 (10 ml)	1
53	24	3 (15 ml)	1½
70	32	4 (20 ml)	2 (or 1 DS tablet)

HOW SUPPLIED: TABLETS, containing 80 mg trimethoprim and 400 mg sulfamethoxazole—bottles of 40, 100, 500 and 1000 tablets; unit dose pack of 100.

ORAL SUSPENSION, containing the equivalent of 40 mg trimethoprim and 200 mg sulfamethoxazole in each teaspoonful (5 ml), cherry flavored—bottle of 450 ml. Also available in double strength, oval-shaped, pink, scored tablets containing 160 mg trimethoprim and 800 mg sulfamethoxazole—Compliance™ Pak of 20, bottle of 60 and unit dose pack of 100.

Looking for a physician?

Here's how to quickly find the perfect fit for your position.

If you're looking for a physician with a specific specialty, the new **AMA Physician Placement Register** is the best source of information on the physicians available. Published quarterly by the AMA Physicians' Placement Service, the Register is the only comprehensive national listing of physicians seeking new practice opportunities.

Fast turnaround! The Register is mailed within 24 hours of receipt of your request. After receiving your selections of the physicians on whom you want further information, full-page computer printouts on each physician will be sent to you within ten days.

New AMA Opportunity Placement Register. As an adjunct to the Physician Register, a coded synopsis of your opportunity will be included in a companion Opportunity Register. Physicians seeking relocation use this Register the same way you use yours, providing you with important additional exposure.

Send for your Register today!

While every precaution is taken to insure accuracy, we cannot guarantee against the possibility of an occasional change or omission in the preparation of this index.

SYNEMOL®
(FLUOCINOLONE ACETONIDE)
CREAM 0.025%

Description SYNEMOL (fluocinolone acetonide) has the chemical name 6α, 9α-difluoro-16α-hydroxyprednisolone-16, 17-acetonide.

The cream contains fluocinolone acetonide 0.25 mg./g. in a water-washable aqueous emollient base of stearyl alcohol, cetyl alcohol, mineral oil, propylene glycol, sorbitan monostearate, polysorbate 60, purified water and citric acid.

Indications Inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions If irritation develops, discontinue the product and institute appropriate therapy.

In the presence of an infection institute the use of an appropriate antifungal or antibacterial agent. If a favorable response does not occur promptly, discontinue the corticosteroid until the infection has been adequately controlled.

If extensive areas are treated or if occlusive technique is used, there will be increased systemic absorption of the corticosteroid and suitable precautions should be taken, particularly in children and infants.

The safety of topical steroids in pregnant women has not absolutely been established. In laboratory animals, increases in incidences of fetal abnormalities have been associated with exposure of gestating females to topical corticosteroids, in some cases at rather low dosage levels. Therefore, drugs of this class should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

SYNEMOL® (fluocinolone acetonide) cream is not for ophthalmic use.

Adverse Reactions Local adverse reactions reported with topical corticosteroids: burning, itching, irritation, dryness, folliculitis, hypertrichosis, acneform eruptions, hypopigmentation, perioral dermatitis, allergic contact dermatitis, maceration of the skin, secondary infection, skin atrophy, striae, miliaria.

How Supplied
SYNEMOL® (fluocinolone acetonide) Cream 0.025%—15, 30 and 60 g. tubes.

a better life with Depakene®
Valproic Acid

or your patients with mixed seizures ncluding absence, or pure absence

lore than just effective eizure control[1]

28 studies of patients with mixed grand mal and sence, 76% of all patients gained significant provement; over one-third became seizure-free. 60 studies involving pure absence, 86% of atients were improved; half became seizure-free.

eedom from social stigmata important too

ith Depakene, social function is unimpeded by ug-induced hirsutism or gingival hyperplasia. tellectual function may improve as more edative drugs are reduced in dosage or ithdrawn. Patients may be able to lead a more ormal life with Depakene than was possible with eir previous drug regimen.

widely useful anticonvulsant

epakene is indicated as sole or adjunctive erapy in both simple and complex absence eizures. It is also indicated for adjunctive eatment of patients with multiple seizure types hich include absence. Clinical response has een especially noteworthy among patients with eneralized tonic-clonic attacks, or with minor otor seizures (e.g., myoclonic movements, kinetic seizures), where combined with absence.

Offering your patients a chance for a better life

Sustained freedom from seizures can mean a drivers license, an active social schedule, involvement in athletic competition—a better life for your patient. Depakene has not been associated with hirsutism or gingival hyperplasia. Sedation has not been a frequent problem. The most common side effect with Depakene is G.I. upset, which usually responds to temporary dosage reduction. Serious side effects, including fatal hepatitis, have occurred.

1. Worldwide studies of Depakene experience (Data refer only to grand mal and/or absence seizures. Since each type was evaluated separately, some patients appear in both groups. Though most of these studies were uncontrolled and had widely differing protocols, their collective data clearly support efficacy of the drug).

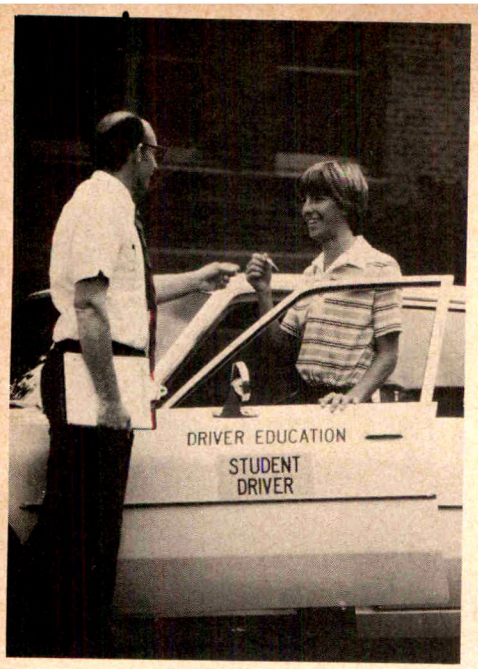
See overleaf for brief summary of prescribing information

Abbott Laboratories,
North Chicago, Illinois 60064

0013326R

Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

Depakene®
Valproic Acid



Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

A BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS: DEPAKENE (valproic acid) is indicated for use as sole and adjunctive therapy in the treatment of simple and complex absence seizures, including petit mal. DEPAKENE may also be used adjunctively in patients with multiple seizure types which include absence seizures.

In accordance with the International Classification of Seizures, simple absence is defined as very brief clouding of the sensorium or loss of consciousness (lasting usually 2-15 seconds), accompanied by certain generalized epileptic discharges without other detectable clinical signs. Complex absence is the term used when other signs are also present.

CONTRAINDICATIONS: DEPAKENE (valproic acid) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: Hepatic failure resulting in fatalities has occurred in patients receiving DEPAKENE. These incidences usually have occurred during the first six months of treatment with DEPAKENE. Liver function tests should be performed prior to therapy and at frequent intervals thereafter. Caution should be observed when administering DEPAKENE to patients with pre-existing hepatic disease.

The drug should be discontinued immediately in the presence of significant hepatic dysfunction, suspected or apparent. The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing the dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher dosages.

Usage in Pregnancy: THE EFFECTS OF DEPAKENE IN HUMAN PREGNANCY ARE UNKNOWN. ANIMAL STUDIES HAVE DEMONSTRATED TERATOGENICITY.

Studies in rats demonstrated placental transfer of the drug. Doses greater than 65 mg/kg/day given to pregnant rats and mice produced skeletal abnormalities in the offspring, primarily involving ribs and vertebrae; doses greater than 150 mg/kg/day given to pregnant rabbits produced fetal resorptions and (primarily) soft-tissue abnormalities in the offspring. In rats a dose-related delay in the onset of parturition was noted. Postnatal growth and survival of the progeny were adversely affected, particularly when drug administration spanned the entire gestation and early lactation period.

THERE ARE MULTIPLE REPORTS IN THE CLINICAL LITERATURE WHICH INDICATE THAT THE USE OF ANTICONVULSANT DRUGS DURING PREGNANCY RESULTS IN AN INCREASED INCIDENCE OF BIRTH DEFECTS IN THE OFFSPRING. ALTHOUGH DATA ARE MORE EXTENSIVE WITH RESPECT TO TRIMETHADIONE, PARAMETHADIONE, PHENYTOIN, AND PHENOBARBITAL, REPORTS INDICATE A POSSIBLE SIMILAR ASSOCIATION WITH THE USE OF OTHER ANTICONVULSANT DRUGS. THEREFORE, ANTICONVULSANT DRUGS SHOULD BE ADMINISTERED TO WOMEN OF CHILDBEARING POTENTIAL ONLY IF THEY ARE CLEARLY SHOWN TO BE ESSENTIAL IN THE MANAGEMENT OF THEIR SEIZURES.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

PRECAUTIONS: *Hepatic dysfunction:* See WARNINGS.

General: Because of reports of thrombocytopenia and platelet aggregation dysfunction, platelet counts and bleeding time determination are recommended before initiating therapy and at periodic intervals. It is recommended that patients receiving DEPAKENE be monitored for platelet count prior to planned surgery. Clinical evidence of hemorrhage, bruising or a disorder of hemostasis/coagulation is an indication for reduction of DEPAKENE dosage or withdrawal of therapy pending investigation.

Since DEPAKENE (valproic acid) may interact with concurrently administered anticonvulsant drugs, periodic serum level determinations of concomitant anticonvulsant drugs are recommended during the early course of therapy. (See Drug Interactions).

DEPAKENE is partially eliminated in the urine as a keto-metabolite which may lead to a false interpretation of the urine ketone test.

Information For Patients: Since DEPAKENE may produce CNS depression, especially when combined with another CNS depressant (e.g., alcohol), patients should be advised not to engage in hazardous occupations, such as driving an automobile or operating dangerous machinery, until it is known that they do not become drowsy from the drug.

Drug Interactions: DEPAKENE may potentiate the CNS depressant activity of alcohol.

THERE IS EVIDENCE THAT DEPAKENE MAY CAUSE AN INCREASE IN SERUM PHENOBARBITAL LEVELS, ALTHOUGH THE MECHANISM OF THE INTERACTION IS UNKNOWN. ALL PATIENTS RECEIVING CONCOMITANT BARBITURATE THERAPY SHOULD BE CLOSELY MONITORED FOR NEUROLOGICAL TOXICITY, SERUM BARBITURATE DRUG LEVELS OBTAINED, IF POSSIBLE, AND THE BARBITURATE DOSAGE DECREASED, IF APPROPRIATE.

Primidone is metabolized into a barbiturate and, therefore, may also be involved in a similar or identical interaction.

THERE IS CONFLICTING EVIDENCE REGARDING THE INTERACTION OF DEPAKENE WITH PHENYTOIN. IT IS NOT KNOWN IF THERE IS A CHANGE IN UNBOUND (FREE) PHENYTOIN SERUM CONCENTRATIONS. THE DOSAGE OF PHENYTOIN SHOULD BE ADJUSTED AS REQUIRED BY THE CLINICAL SITUATION.

THE CONCOMITANT USE OF VALPROIC ACID AND CLONAZEPAM MAY PRODUCE ABSENCE STATUS.

Caution is recommended when DEPAKENE (valproic acid) is administered with drugs affecting coagulation, e.g., aspirin and warfarin. (See ADVERSE REACTIONS).

Carcinogenesis, Mutagenesis: There has been insufficient study of the drug in animals to determine whether it has carcinogenic potential. Carcinogenicity studies in rats and mice are currently in progress.

Mutagenesis studies on DEPAKENE have been performed using bacterial and mammalian systems. These studies have provided no evidence of a mutagenic potential for DEPAKENE.

Pregnancy: See WARNINGS.

Nursing Mothers: DEPAKENE is excreted in breast milk. It is not known what effect this would have on a nursing infant. As a general rule, nursing should not be undertaken while a patient is receiving DEPAKENE.

Fertility: Chronic toxicity studies in juvenile and adult rats and dogs demonstrated reduced spermatogenesis and testicular atrophy at doses greater than 200 mg/kg/day in rats and greater than 90 mg/kg/day in dogs. Segment I fertility studies in rats have shown doses up to 350 mg/kg/day for 60 days to have no effect on fertility. THE EFFECT OF DEPAKENE (VALPROIC ACID) ON THE DEVELOPMENT OF THE TESTES AND ON SPERM PRODUCTION AND FERTILITY IN HUMANS IS UNKNOWN.

ADVERSE REACTIONS: Since DEPAKENE (valproic acid) has usually been used with other anticonvulsant drugs, it is not possible, in most cases, to determine whether the following adverse reactions can be ascribed to DEPAKENE alone, or the combination of drugs.

Gastrointestinal: The most commonly reported side effects at the initiation of therapy are nausea, vomiting and indigestion. These effects are usually transient and rarely require discontinuation of therapy. Diarrhea, abdominal cramps and constipation have been reported. Both anorexia with some weight loss and increased appetite with weight gain have also been reported.

CNS Effects: Sedative effects have been noted in patients receiving valproic acid alone but are found most often in patients receiving combination therapy. Sedation usually disappears upon reduction of other anticonvulsant medication. Ataxia, headache, nystagmus, diplopia, asterixis, "spots before eyes", tremo dysarthria, dizziness, and incoordination have rarely been note Rare cases of coma have been noted in patients also on phenoba bital.

Dermatologic: Transient increases in hair loss have been ol served. Skin rash and petechiae have rarely been noted.

Psychiatric: Emotional upset, depression, psychosis, aggressio hyperactivity and behavioral deterioration have been reported.

Musculoskeletal: Weakness has been reported.

Hematopoietic: Thrombocytopenia has been reported. Valproi acid inhibits the secondary phase of platelet aggregation. (Se DRUG INTERACTIONS). This may be reflected in altered bleedin time. Bruising, hematoma formation and frank hemorrhage hav been reported. Relative lymphocytosis and hypofibrinogenemi have been noted. Leukopenia and eosinophilia have also been re ported.

Hepatic: Increases in serum alkaline phosphatase and elevation of serum glutamic oxaloacetic transaminase (SGOT) have bee noted. Elevation of SGOT may be dose related. Elevations of SGP and LDH have been noted less frequently. Isolated cases of sever hepatotoxicity have been reported but do not appear dose related (See WARNINGS).

OVERDOSAGE: A single case of overdosage with valproic aci has been reported. After ingesting 36 grams in combination wit phenobarbital and phenytoin, the patient presented in deep coma An electroencephalogram recorded diffuse slowing, compatibl with the state of consciousness. The patient made an uneventfu recovery.

Since DEPAKENE is absorbed very rapidly, gastric lavage may be of limited value. General supportive measures should be applied with particular attention being given to the maintenance of adequate urinary output.

DOSAGE AND ADMINISTRATION: DEPAKENE (valproic acid) is administered orally. The recommended initial dose is 15 mg/kg/day, increasing at one week intervals by 5 to 10 mg/kg/day, until seizures are controlled or side effects preclude further increases. The maximum recommended dosage is 60 mg/kg/day. If the total daily dose exceeds 250 mg, it should be given in a divided regimen.

The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increased dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher doses.

The following table is a guide for the initial daily dose of DEPAKENE (valproic acid) (15 mg/kg/day):

Weight (kg)	Weight (lb)	Total Daily Dose (mg)	Number of Capsules or Teaspoonfuls of Syrup Dose 1	Dose 2	Dose 3
10 - 24.9	22 - 54.9	250	0	0	1
25 - 39.9	55 - 87.9	500	1	0	1
40 - 59.9	88 - 131.9	750	1	1	1
60 - 74.9	132 - 164.9	1,000	1	1	2
75 - 89.9	165 - 197.9	1,250	2	1	2

A good correlation has not been established between daily dose, serum level and therapeutic effect, however, therapeutic serum levels for most patients will range from 50 to 100 mcg/ml. Occasional patients may be controlled with serum levels lower or higher than this range.

As the DEPAKENE dosage is titrated upward, blood levels of phenobarbital and/or phenytoin may be affected. (See PRECAUTIONS).

Patients who experience G.I. irritation may benefit from administration of the drug with food or by slowly building up the dose from an initial low level.

THE CAPSULES SHOULD BE SWALLOWED WITHOUT CHEWING TO AVOID LOCAL IRRITATION OF THE MOUTH AND THROAT.

HOW SUPPLIED: DEPAKENE (valproic acid) is available as orange-colored soft gelatin capsules of 250 mg valproic acid in bottles of 100 capsules (**NDC** 0074-5681-13), and as a red syrup containing the equivalent of 250 mg valproic acid per 5 ml as the sodium salt in bottles of 16 ounces (**NDC** 0074-5682-16).

AMA AMERICAN MEDICAL ASSOCIATION

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY

OTITIS MEDIA (ACUTE): AURALGAN is indicated for relief of pain and reduction of inflammation in the congestive and serous stages of acute otitis media. It is effective adjuvant therapy when antibiotics or sulfonamides are administered systemically.

Administration: Otitis media (acute): Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching ear with dropper. Then, moisten cotton pledget with AURALGAN and insert into the meatus. Repeat every one to two hours (or three or four times a day).

REMOVAL OF CERUMEN: AURALGAN facilitates the removal of excessive or impacted cerumen.

Administration for Removal of Cerumen: Instill AURALGAN three times daily for two days to help detach cerumen from wall of canal and facilitate removal of plug. Irrigate with warm water.

Note: Keep well closed. Do not rinse dropper after use.

SUPPLIED: No. 1000 – AURALGAN Otic Solution, in package containing 15 ml (1/2 fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY.
ON PRESCRIPTION ONLY.

Expressly for kids with colds that cough*

orange-pineapple flavored

Tuss-Ornade® cough/cold liquid

Each 5 ml. teaspoonful contains 5 mg. caramiphen edisylate; 2 mg. chlorpheniramine maleate; 15 mg. phenylpropanolamine hydrochloride; isopropamide iodide equivalent to 0.75 mg. of isopropamide; and alcohol, 7.5%.

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

* **Indications**

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Lacking in substantial evidence of effectiveness as a fixed combination: For relief from coughing, upper respiratory congestion and hypersecretion associated with the common cold, sinusitis, vasomotor rhinitis and allergic rhinitis.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Hypersensitivity to any component; concurrent MAO inhibitor therapy; severe hypertension; bronchial asthma; coronary artery disease; stenosing peptic ulcer; pyloroduodenal or bladder neck obstruction. Do not use 'Tuss-Ornade' Liquid in children less than six months of age or under 15 lbs. in weight. Do not use 'Tuss-Ornade' *Spansule* capsules in children under 12 years of age.

Warnings: Warn vehicle or machine operators of possible drowsiness. Warn patients of possible additive effects of alcohol and other C.N.S. depressants.

Usage in Pregnancy: Use in pregnancy, nursing mothers and women who might bear children only when potential benefits have been weighed against possible hazards. An inhibitory effect on lactation may occur.

Effect on PBI Determination and I^{131} Uptake: The iodine in isopropamide iodide may alter PBI test results and will suppress I^{131} uptake; use thyroid tests unaffected by exogenous iodides.

Precautions: Use with caution in persons with cardiovascular disease, glaucoma, prostatic hypertrophy, hyperthyroidism.

Adverse Reactions: Drowsiness; excessive dryness of nose, throat or mouth; nervousness, insomnia; nausea, vomiting, diarrhea; rash; dizziness; weakness; tightness of chest; angina pain; abdominal pain; irritability; palpitation; headache; incoordination; tremor; difficulty in urination; thrombocytopenia, leukopenia; convulsions; hypertension, hypotension; anorexia; constipation; visual disturbances; iodine toxicity (acne, parotitis); dysuria; epigastric distress.

Supplied: 'Tuss-Ornade' Liquid: An orange-pineapple flavored liquid in 16 fl. oz. bottles. For patients 12 years or older, 'Tuss-Ornade' *Spansule* capsules (each capsule contains 20 mg. caramiphen edisylate; 8 mg. chlorpheniramine maleate; 50 mg. phenylpropanolamine HCl; and isopropamide iodide equivalent to 2.5 mg. of isopropamide), in bottles of 50 and 500 capsules.

Change of Address: POSTMASTER, send address changes to Helen R. Mazur, Director, Circulation-Fulfillment. Notification of address changes should be sent at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AMERICAN JOURNAL OF DISEASES OF CHILDREN (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

ACTIFED-C® Expectorant ℞

Each 5 cc teaspoonful contains: codeine phosphate 10 mg (Warning—may be habit-forming); Actidil® brand triprolidine HCl 2 mg; Sudafed® brand pseudoephedrine HCl 30 mg; guaifenesin 100 mg. Preservatives are methylparaben 0.1% and sodium benzoate 0.1%.

With the cough-stopping power of codeine.

Controls Excessive Coughing Without Preventing Productive Expectoration

Persistent, repetitive, dry coughs can be a problem in the pediatric patient, particularly at night when it often disturbs sleep. Actifed-C is made for this type of cough.

It contains codeine to reduce severity and persistence plus guaifenesin to liquefy and ease the expulsion of mucus. Moreover, Actifed-C is the only cough medication that contains triprolidine and pseudoephedrine... the decongestant/antihistamine combination that has been part of the NASA Space Medicine Kit since 1968.

Indications: Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Lacking substantial evidence of effectiveness as a fixed combination": For the symptomatic relief of cough in conditions such as: the common cold, acute bronchitis, allergic asthma, bronchiolitis, croup, emphysema, tracheobronchitis.

Final classification of the less-than-effective indications requires further investigation.

Warning: Use in Pregnancy: Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus.

Precautions: Although pseudoephedrine hydrochloride causes virtually no pressor effect in normotensive patients, it should be used with caution in patients with hypertension. In addition, even though triprolidine hydrochloride produces only a low incidence of drowsiness, appropriate precautions should be observed.

Side Effects: The great majority of patients will not have any side effects. Only certain patients, sensitive to one or another of the ingredients, may note mild stimulation or mild sedation.

Supplied: Bottles of 1 pint. Complete literature available on request from Professional Services Dept. PML.

Not recommended for use in children under 2 years of age.

Finally going for a license...

a better life with Depakene®
Valproic Acid

For your patients with mixed seizures including absence, or pure absence

More than just effective seizure control[1]

In 28 studies of patients with mixed grand mal and absence, 76% of all patients gained significant improvement; over one-third became seizure-free. In 60 studies involving pure absence, 86% of patients were improved; half became seizure-free.

Freedom from social stigmata is important too

With Depakene, social function is unimpeded by drug-induced hirsutism or gingival hyperplasia. Intellectual function may improve as more sedative drugs are reduced in dosage or withdrawn. Patients may be able to lead a more normal life with Depakene than was possible with their previous drug regimen.

A widely useful anticonvulsant

Depakene is indicated as sole or adjunctive therapy in both simple and complex absence seizures. It is also indicated for adjunctive treatment of patients with multiple seizure types which include absence. Clinical response has been especially noteworthy among patients with generalized tonic-clonic attacks, or with minor motor seizures (e.g., myoclonic movements, akinetic seizures), where combined with absence.

Offering your patients a chance for a better life

Sustained freedom from seizures can mean a drivers license, an active social schedule, involvement in athletic competition—a better life for your patient. Depakene has not been associated with hirsutism or gingival hyperplasia. Sedation has not been a frequent problem. The most common side effect with Depakene is G.I. upset, which usually responds to temporary dosage reduction. Serious side effects, including fatal hepatitis, have occurred.

1. Worldwide studies of Depakene experience (Data refer only to grand mal and/or absence seizures. Since each type was evaluated separately, some patients appear in both groups. Though most of these studies were uncontrolled and had widely differing protocols, their collective data clearly support efficacy of the drug).

See overleaf for brief summary of prescribing information

Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

A BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS: DEPAKENE (valproic acid) is indicated for use as sole and adjunctive therapy in the treatment of simple and complex absence seizures, including petit mal. DEPAKENE may also be used adjunctively in patients with multiple seizure types which include absence seizures.

In accordance with the International Classification of Seizures, simple absence is defined as very brief clouding of the sensorium or loss of consciousness (lasting usually 2-15 seconds), accompanied by certain generalized epileptic discharges without other detectable clinical signs. Complex absence is the term used when other signs are also present.

CONTRAINDICATIONS: DEPAKENE (valproic acid) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: Hepatic failure resulting in fatalities has occurred in patients receiving DEPAKENE. These incidences usually have occurred during the first six months of treatment with DEPAKENE. Liver function tests should be performed prior to therapy and at frequent intervals thereafter. Caution should be observed when administering DEPAKENE to patients with pre-existing hepatic disease.

The drug should be discontinued immediately in the presence of significant hepatic dysfunction, suspected or apparent. The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing the dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher dosages.

Usage in Pregnancy: THE EFFECTS OF DEPAKENE IN HUMAN PREGNANCY ARE UNKNOWN. ANIMAL STUDIES HAVE DEMONSTRATED TERATOGENICITY.

Studies in rats demonstrated placental transfer of the drug. Doses greater than 65 mg/kg/day given to pregnant rats and mice produced skeletal abnormalities in the offspring, primarily involving ribs and vertebrae; doses greater than 150 mg/kg/day given to pregnant rabbits produced fetal resorptions and (primarily) soft-tissue abnormalities in the offspring. In rats a dose-related delay in the onset of parturition was noted. Postnatal growth and survival of the progeny were adversely affected, particularly when drug administration spanned the entire gestation and early lactation period.

THERE ARE MULTIPLE REPORTS IN THE CLINICAL LITERATURE WHICH INDICATE THAT THE USE OF ANTICONVULSANT DRUGS DURING PREGNANCY RESULTS IN AN INCREASED INCIDENCE OF BIRTH DEFECTS IN THE OFFSPRING. ALTHOUGH DATA ARE MORE EXTENSIVE WITH RESPECT TO TRIMETHADIONE, PARAMETHADIONE, PHENYTOIN, AND PHENOBARBITAL, REPORTS INDICATE A POSSIBLE SIMILAR ASSOCIATION WITH THE USE OF OTHER ANTICONVULSANT DRUGS. THEREFORE, ANTICONVULSANT DRUGS SHOULD BE ADMINISTERED TO WOMEN OF CHILDBEARING POTENTIAL ONLY IF THEY ARE CLEARLY SHOWN TO BE ESSENTIAL IN THE MANAGEMENT OF THEIR SEIZURES.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

PRECAUTIONS: *Hepatic dysfunction:* See WARNINGS.

General: Because of reports of thrombocytopenia and platelet aggregation dysfunction, platelet counts and bleeding time determination are recommended before initiating therapy and at periodic intervals. It is recommended that patients receiving DEPAKENE be monitored for platelet count prior to planned surgery. Clinical evidence of hemorrhage, bruising or a disorder of hemostasis/coagulation is an indication for reduction of DEPAKENE dosage or withdrawal of therapy pending investigation.

Since DEPAKENE (valproic acid) may interact with concurrently administered anticonvulsant drugs, periodic serum level determinations of concomitant anticonvulsant drugs are recommended during the early course of therapy. (See Drug Interactions).

DEPAKENE is partially eliminated in the urine as a keto-metabolite which may lead to a false interpretation of the urine ketone test.

Information For Patients: Since DEPAKENE may produce CNS depression, especially when combined with another CNS depressant (e.g., alcohol), patients should be advised not to engage in hazardous occupations, such as driving an automobile or operating dangerous machinery, until it is known that they do not become drowsy from the drug.

Drug Interactions: DEPAKENE may potentiate the CNS depressant activity of alcohol.

THERE IS EVIDENCE THAT DEPAKENE MAY CAUSE AN INCREASE IN SERUM PHENOBARBITAL LEVELS, ALTHOUGH THE MECHANISM OF THE INTERACTION IS UNKNOWN. ALL PATIENTS RECEIVING CONCOMITANT BARBITURATE THERAPY SHOULD BE CLOSELY MONITORED FOR NEUROLOGICAL TOXICITY, SERUM BARBITURATE DRUG LEVELS OBTAINED, IF POSSIBLE, AND THE BARBITURATE DOSAGE DECREASED, IF APPROPRIATE.

Primidone is metabolized into a barbiturate and, therefore, may also be involved in a similar or identical interaction.

THERE IS CONFLICTING EVIDENCE REGARDING THE INTERACTION OF DEPAKENE WITH PHENYTOIN. IT IS NOT KNOWN IF THERE IS A CHANGE IN UNBOUND (FREE) PHENYTOIN SERUM CONCENTRATIONS. THE DOSAGE OF PHENYTOIN SHOULD BE ADJUSTED AS REQUIRED BY THE CLINICAL SITUATION.

THE CONCOMITANT USE OF VALPROIC ACID AND CLONAZEPAM MAY PRODUCE ABSENCE STATUS.

Caution is recommended when DEPAKENE (valproic acid) is administered with drugs affecting coagulation, e.g., aspirin and warfarin. (See ADVERSE REACTIONS).

Carcinogenesis, Mutagenesis: There has been insufficient study of the drug in animals to determine whether it has carcinogenic potential. Carcinogenicity studies in rats and mice are currently in progress.

Mutagenesis studies on DEPAKENE have been performed using bacterial and mammalian systems. These studies have provided no evidence of a mutagenic potential for DEPAKENE.

Pregnancy: See WARNINGS.

Nursing Mothers: DEPAKENE is excreted in breast milk. It is not known what effect this would have on a nursing infant. As a general rule, nursing should not be undertaken while a patient is receiving DEPAKENE.

Fertility: Chronic toxicity studies in juvenile and adult rats and dogs demonstrated reduced spermatogenesis and testicular atrophy at doses greater than 200 mg/kg/day in rats and greater than 90 mg/kg/day in dogs. Segment I fertility studies in rats have shown doses up to 350 mg/kg/day for 60 days to have no effect on fertility. THE EFFECT OF DEPAKENE (VALPROIC ACID) ON THE DEVELOPMENT OF THE TESTES AND ON SPERM PRODUCTION AND FERTILITY IN HUMANS IS UNKNOWN.

ADVERSE REACTIONS: Since DEPAKENE (valproic acid) has usually been used with other anticonvulsant drugs, it is not possible, in most cases, to determine whether the following adverse reactions can be ascribed to DEPAKENE alone, or the combination of drugs.

Gastrointestinal: The most commonly reported side effects at the initiation of therapy are nausea, vomiting and indigestion. These effects are usually transient and rarely require discontinuation of therapy. Diarrhea, abdominal cramps and constipation have been reported. Both anorexia with some weight loss and increased appetite with weight gain have also been reported.

CNS Effects: Sedative effects have been noted in patients receiving valproic acid alone but are found most often in patients receiving combination therapy. Sedation usually disappears upon reduction of other anticonvulsant medication. Ataxia, headache, nystagmus, diplopia, asterixis, "spots before eyes", tremor, dysarthria, dizziness, and incoordination have rarely been noted. Rare cases of coma have been noted in patients also on phenobarbital.

Dermatologic: Transient increases in hair loss have been observed. Skin rash and petechiae have rarely been noted.

Psychiatric: Emotional upset, depression, psychosis, aggression, hyperactivity and behavioral deterioration have been reported.

Musculoskeletal: Weakness has been reported.

Hematopoietic: Thrombocytopenia has been reported. Valproic acid inhibits the secondary phase of platelet aggregation. (See DRUG INTERACTIONS). This may be reflected in altered bleeding time. Bruising, hematoma formation and frank hemorrhage have been reported. Relative lymphocytosis and hypofibrinogenemia have been noted. Leukopenia and eosinophilia have also been reported.

Hepatic: Increases in serum alkaline phosphatase and elevations of serum glutamic oxaloacetic transaminase (SGOT) have been noted. Elevation of SGOT may be dose related. Elevations of SGPT and LDH have been noted less frequently. Isolated cases of severe hepatotoxicity have been reported but do not appear dose related. (See WARNINGS).

OVERDOSAGE: A single case of overdosage with valproic acid has been reported. After ingesting 36 grams in combination with phenobarbital and phenytoin, the patient presented in deep coma. An electroencephalogram recorded diffuse slowing, compatible with the state of consciousness. The patient made an uneventful recovery.

Since DEPAKENE is absorbed very rapidly, gastric lavage may be of limited value. General supportive measures should be applied with particular attention being given to the maintenance of adequate urinary output.

DOSAGE AND ADMINISTRATION: DEPAKENE (valproic acid) is administered orally. The recommended initial dose is 15 mg/kg/day, increasing at one week intervals by 5 to 10 mg/kg/day, until seizures are controlled or side effects preclude further increases. The maximum recommended dosage is 60 mg/kg/day. If the total daily dose exceeds 250 mg, it should be given in a divided regimen.

The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increased dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher doses.

The following table is a guide for the initial daily dose of DEPAKENE (valproic acid) (15 mg/kg/day):

Weight (kg)	Weight (lb)	Total Daily Dose (mg)	Number of Capsules or Teaspoonfuls of Syrup Dose 1	Dose 2	Dose 3
10 - 24.9	22 - 54.9	250	0	0	1
25 - 39.9	55 - 87.9	500	1	0	1
40 - 59.9	88 - 131.9	750	1	1	1
60 - 74.9	132 - 164.9	1,000	1	1	2
75 - 89.9	165 - 197.9	1,250	2	1	2

A good correlation has not been established between daily dose, serum level and therapeutic effect, however, therapeutic serum levels for most patients will range from 50 to 100 mcg/ml. Occasional patients may be controlled with serum levels lower or higher than this range.

As the DEPAKENE dosage is titrated upward, blood levels of phenobarbital and/or phenytoin may be affected. (See PRECAUTIONS).

Patients who experience G.I. irritation may benefit from administration of the drug with food or by slowly building up the dose from an initial low level.

THE CAPSULES SHOULD BE SWALLOWED WITHOUT CHEWING TO AVOID LOCAL IRRITATION OF THE MOUTH AND THROAT.

HOW SUPPLIED: DEPAKENE (valproic acid) is available as orange-colored soft gelatin capsules of 250 mg valproic acid in bottles of 100 capsules (**NDC** 0074-5681-13), and as a red syrup containing the equivalent of 250 mg valproic acid per 5 ml as the sodium salt in bottles of 16 ounces (**NDC** 0074-5682-16).

0013326

ABBOTT

Instructions for Authors

General Information.—Send manuscripts by first-class (not registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation

All the elements of a manuscript should be submitted in **triplicate, double-spaced throughout.** Use heavy-duty white bond paper, 22 × 28-cm, and 4-cm margins. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda

Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor

Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References

These must be listed in order of their appearance in the text, and typed double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 131:295-296, 1977.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons Inc, 1965, pp 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders Co, 1974, pp 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations

Submit in triplicate, unmounted, and untrimmed. Send only high contrast glossy prints (not photocopies or original artwork); preferred size 12.5 × 18-cm. Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title

In pediatric infections

Septra®

Each teaspoonful (5 ml) contains:
40 mg trimethoprim and 200 mg sulfamethoxazole

Suspension B.I.D.

Acute
Otitis
Media

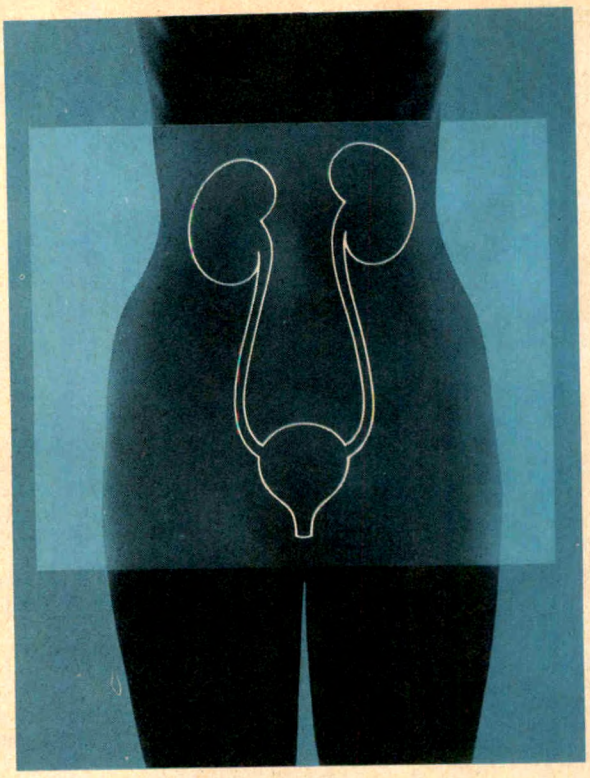
where the action is.

In acute otitis media

Septra Suspension provides effective antibacterial action against susceptible strains of H influenzae and S pneumoniae (D pneumoniae), the pathogens most likely to cause acute otitis media in children.

Septra Suspension is useful in many patients, but especially in those with penicillin allergy or with infections caused by ampicillin-resistant H influenzae. Limited clinical data are presently available on the effectiveness of treatment of acute otitis media with Septra when the infection is due to H influenzae resistant to ampicillin. However, in vitro data is highly favorable; when over 200 strains of ampicillin-resistant H influenzae were tested, all proved susceptible to TMP/SMX.*

And unlike most other antibacterials for the treatment of acute otitis media, Septra Suspension is administered on a convenient b.i.d. dosage schedule. The cherry-flavored suspension is well accepted by children.



In recurrent urinary tract infections

Septra Suspension provides effective antibacterial action in urine and blood against susceptible strains of E coli, Klebsiella-Enterobacter and Proteus. Whether the infection centers in the kidneys or bladder, Septra Suspension maintains effective levels at the site of the infection with just two doses a day.

Adequate fluid intake should be maintained and frequent urinalyses with careful microscopic examination performed during Septra therapy. Septra is contraindicated in infants under two months of age.

*In vitro data do not necessarily correlate with clinical results. Data on file, Burroughs Wellcome Co.
NOTE: Septra should not be used in the treatment of streptococcal pharyngitis.

Please see prescribing information on next page.

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

Septra® Suspension B.I.D.

Each teaspoonful (5 ml) contains: 40 mg trimethoprim and 200 mg sulfamethoxazole

Septra® DS B.I.D.

Each tablet contains: 160 mg trimethoprim and 800 mg sulfamethoxazole

Septra® DS Tablets Double Strength
Septra® Tablets
Septra® Suspension

INDICATIONS AND USAGE:
URINARY TRACT INFECTIONS: **For the treatment of urinary tract infections due to susceptible strains of the following organisms:** *Escherichia coli, Klebsiella-Enterobacter, Proteus mirabilis, Proteus vulgaris, Proteus morganii.* **It is recommended that initial episodes of uncomplicated urinary tract infections be treated with a single effective antibacterial agent rather than the combination.**

NOTE: Currently, the increasing frequency of resistant organisms is a limitation of the usefulness of all antibacterial agents, especially in the treatment of these urinary tract infections.

ACUTE OTITIS MEDIA: **For the treatment of acute otitis media in children due to susceptible strains of** *Haemophilus influenzae* **or** *Streptococcus pneumoniae* **when in the judgment of the physician Septra offers some advantage over the use of other antimicrobial agents. Limited clinical information is presently available on the effectiveness of treatment of otitis media with Septra when the infection is due to** *Haemophilus influenzae* **resistant to ampicillin. To date, there are limited data on the safety of repeated use of Septra in children under two years of age. Septra is not indicated for prophylactic or prolonged administration in otitis media at any age.**

SHIGELLOSIS: **For the treatment of enteritis caused by susceptible strains of** *Shigella flexneri* **and** *Shigella sonnei* **when antibacterial therapy is indicated.**

PNEUMOCYSTIS CARINII **PNEUMONITIS: For the treatment of documented** *Pneumocystis carinii* **pneumonitis. To date, this drug has been tested only in patients 9 months to 16 years of age who were immunosuppressed by cancer therapy.**

CONTRAINDICATIONS: Hypersensitivity to trimethoprim or sulfonamides. Pregnancy and during the nursing period. Infants less than two months of age.

WARNINGS: SEPTRA SHOULD NOT BE USED IN THE TREATMENT OF STREPTOCOCCAL PHARYNGITIS.

Clinical studies have documented that patients with Group A β-hemolytic streptococcal tonsillopharyngitis have a greater incidence of bacteriologic failure when treated with Septra than do those patients treated with penicillin as evidenced by failure to eradicate this organism from the tonsillopharyngeal area.

Deaths associated with administration of sulfonamides have been reported from hypersensitivity reactions, agranulocytosis, aplastic anemia and other blood dyscrasias. Experience with trimethoprim alone is much more limited, but occasional interference with hematopoiesis has been reported as well as an increased incidence of thrombopenia with purpura in elderly patients on certain diuretics, primarily thiazides.

Sore throat, fever, pallor, purpura or jaundice may be early signs of serious blood disorders. Frequent CBCs are recommended; therapy should be discontinued if a significant reduction in the count of any formed blood element is noted.

PRECAUTIONS: Use with caution in patients with impaired renal or hepatic function, possible folate deficiency, severe allergy or bronchial asthma. In glucose-6-phosphate dehydrogenase-deficient individuals, hemolysis may occur (frequently dose-related). During therapy, maintain adequate fluid intake and perform frequent urinalyses with careful microscopic examination and renal function tests, particularly where there is impaired renal function.

Since Septra may prolong prothrombin time in patients on warfarin, coagulation time should be reassessed when Septra is given.

ADVERSE REACTIONS: All major reactions to sulfonamides and trimethoprim are included, even if not reported with Septra. *Blood Dyscrasias:* Agranulocytosis, aplastic anemia, megaloblastic anemia, thrombopenia, leukopenia, hemolytic anemia, purpura, hypoprothrombinemia and methemoglobinemia. *Allergic Reactions:* Erythema multiforme, Stevens-Johnson syndrome, generalized skin eruptions, epidermal necrolysis, urticaria, serum sickness, pruritus, exfoliative dermatitis, anaphylactoid reactions, periorbital edema, conjunctival and scleral injection, photosensitization, arthralgia and allergic myocarditis. *Gastrointestinal Reactions:* Glossitis, stomatitis, nausea, emesis, abdominal pains, hepatitis, diarrhea and pancreatitis. *C.N.S. Reactions:* Headache, peripheral neuritis, mental depression, convulsions, ataxia, hallucinations, tinnitus, vertigo, insomnia, apathy, fatigue, muscle weakness and nervousness. *Miscellaneous Reactions:* Drug fever, chills, and toxic nephrosis with oliguria and anuria. Periarteritis nodosa and L. E. phenomenon have occurred.

Due to certain chemical similarities to some goitrogens, diuretics (acetazolamide and the thiazides) and oral hypoglycemic agents, sulfonamides have caused rare instances of goiter production, diuresis and hypoglycemia; cross-sensitivity may exist with these agents. In rats, long-term administration of sulfonamides has produced thyroid malignancies.

DOSAGE AND ADMINISTRATION: Not recommended for use in infants less than two months of age.

URINARY TRACT INFECTIONS AND SHIGELLOSIS IN ADULTS AND CHILDREN AND ACUTE OTITIS MEDIA IN CHILDREN:

Adults: The usual adult dosage for the treatment of urinary tract infections is two tablets or four teaspoonfuls (20 ml) every 12 hours for 10 to 14 days. An identical daily dosage is used for 5 days in the treatment of shigellosis.

Children: The recommended dose for children with urinary tract infections or acute otitis media is 8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole per 24 hours, given in two divided doses every 12 hours for 10 days. An identical daily dosage is used for 5 days in the treatment of shigellosis. The following table is a guideline for the attainment of this dosage using Septra Tablets or Suspension.

Children: Two months of age or older:

Weight		Dose —every 12 hours	
lb	kg	Teaspoonfuls	Tablets
22	10	1 (5 ml)	½
44	20	2 (10 ml)	1
66	30	3 (15 ml)	1½
88	40	4 (20 ml)	2 (or 1 DS tablet)

For patients with renal impairment:

Creatinine Clearance (ml/min)	Recommended Dosage Regimen
Above 30	Usual Standard Regimen
15-30	Half of the usual dosage regimen
Below 15	Use Not Recommended

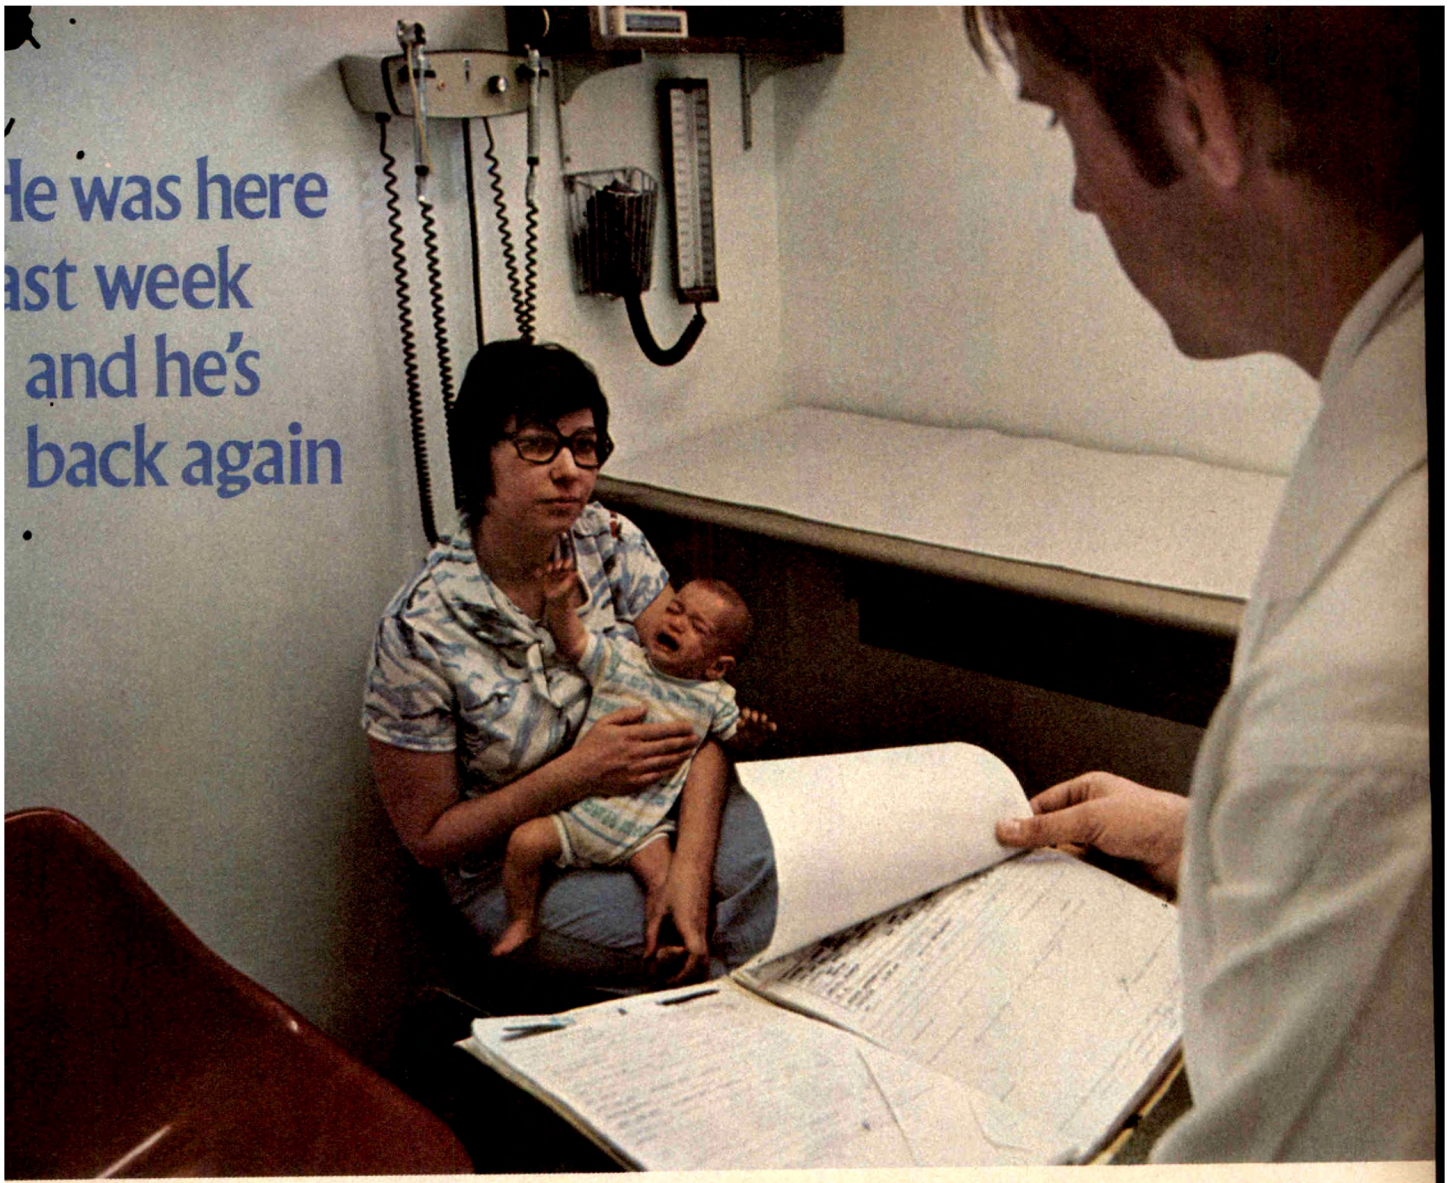
PNEUMOCYSTIS CARINII **PNEUMONITIS:**
The recommended dosage for patients with documented *Pneumocystis carinii* pneumonitis is 20 mg/kg trimethoprim and 100 mg/kg sulfamethoxazole per 24 hours given in equally divided doses every 6 hours for 14 days. The following table is a guideline for the attainment of this dosage in children.

Weight		Dose —every 6 hours	
lb	kg	Teaspoonfuls	Tablets
18	8	1 (5 ml)	½
35	16	2 (10 ml)	1
53	24	3 (15 ml)	1½
70	32	4 (20 ml)	2 (or 1 DS tablet)

HOW SUPPLIED: TABLETS, containing 80 mg trimethoprim and 400 mg sulfamethoxazole—bottles of 40, 100, 500 and 1000 tablets; unit dose pack of 100.

ORAL SUSPENSION, containing the equivalent of 40 mg trimethoprim and 200 mg sulfamethoxazole in each teaspoonful (5 ml), cherry flavored—bottle of 450 ml. Also available in double strength, oval-shaped, pink, scored tablets containing 160 mg trimethoprim and 800 mg sulfamethoxazole—Compliance™ Pak of 20, bottle of 60 and unit dose pack of 100.

ONE HUNDRED YEARS WELLCOME
Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709



Have you ruled out cow-milk sensitivity?

The physical symptoms are many and varied: diarrhea, colic, eczema, asthma, vomiting, bronchitis, rhinitis. They can be coupled with behavioral symptoms: repeated refusal of the nursing bottle . . . general fussiness.[1-3]

Alone or together, the manifestations of milk sensitivity are an unnecessary burden for the infant . . . and parents. More important, if unchecked the allergic syndromes can lead to failure to thrive and other serious health problems.[4]

With Isomil® Soy Protein Formula you can avoid the symptoms of milk sensitivity and help confirm your initial diagnosis.

Moreover, Isomil promotes normal growth.[2,5] It looks like milk, it pours like milk and has a pleasant aroma, which help insure acceptability. Unlike milk, Isomil is lactose free. It avoids the possibility of prolonged or recurring diarrhea caused by lactose intolerance.

Consider the possibility of milk sensitivity when associated symptoms are presented. "A high index of suspicion" is essential to its prompt detection.[2,6]

ROSS LABORATORIES
COLUMBUS, OHIO 43216
Division of Abbott Laboratories, USA

Get them on their feet again!

When winter colds are at their worst, Naldecon® is at its best!

(antihistamine/decongestant)

Winter colds can get even the best of sports down. But Naldecon® (antihistamine/decongestant) can get them up and going again with fast symptomatic relief!

With balanced formulation for maximum relief and minimum side effects.

Naldecon combines antihistamines from two chemical classes, as well as two decongestants, to offer prompt symptomatic relief and minimize side effects. That's why it's the ideal choice for busy, active patients who aren't going to let a cold stop them.

An ethanolamine for long-lasting antihistamine activity

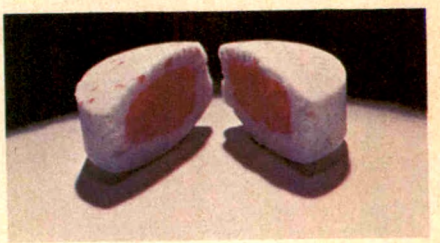
An alkylamine for minimal antihistamine drowsiness

Phenylpropanolamine for prolonged decongestant effectiveness

Phenylephrine for additional decongestant action with little or no C.N.S. stimulation.

With a unique tablet designed for easy titrating and hours of sustained relief.

With Naldecon tablets, adjusting dosage without losing the convenience of sustained relief is a snap! The unique Naldecon tablet is scored so that just a little thumb pressure on each half of the tablet breaks it neatly in two. Half tablet or whole, the outer layer rapidly dissolves for prompt effectiveness and the slow-release inner core provides additional hours of relief.



With enough dosage forms to keep the entire family skiing.

Naldecon's full line of forms for all ages includes "kid-tested and flavor-approved" pediatric liquids.

- Adult tablets and syrup.
- Pediatric syrup for infants and children, 6 months to 12 years old.
- Pediatric drops for infants and children, 3 months to 6 years old.

Naldecon® salutes the world's best.

XIII OLYMPIC WINTER GAMES LAKE PLACID 1980

The world's best winter athletes gather in Lake Placid this year for the quadrennial spectacle of the Olympic Winter Games. Bristol Laboratories takes great pride in having Naldecon designated Official Supplier to these XIII Olympic Winter Games.
We salute the splendid amateur athletes whose memorable feats are once again an inspiration to all of us who have trouble staying on our feet in the winter.

Naldecon®
(antihistamine/decongestant)

Official Supplier to the XIII Olympic Winter Games in Lake Placid, New York.

XIII OLYMPIC WINTER GAMES LAKE PLACID 1980

Only Naldecon® offers the winter cold sufferer the effectiveness of *two* antihistamines and *two* decongestants, proportioned to minimize their undesirable side effects.

Naldecon® has:

- **Staying power.** Sustained release: an outer layer fo immediate relief, an inner core for hours more.
- **Flexibility.** Dosage forms for all ages and a unique scored tablet for fractionalized dosage, without losing the sustained release.
- **Balance.** Formulated to provide maximum effectiveness with minimum side effects.

NALDECON® Tablets, Syrup, Pediatric Drops, and Pediatric Syrup For Oral Use Only

5600DIMO-11 1/78

DESCRIPTION:

Each sustained-action tablet contains:	For immediate action	For delayed action	Total content
Phenylpropanolamine hydrochloride	20.0 mg.	20.0 mg.	40.0 mg.
Phenylephrine hydrochloride	5.0 mg.	5.0 mg.	10.0 mg.
Phenyltoloxamine citrate	7.5 mg.	7.5 mg.	15.0 mg.
Chlorpheniramine maleate	2.5 mg.	2.5 mg.	5.0 mg.

Each teaspoonful (5 ml.) of syrup contains:

Phenylpropanolamine hydrochloride	20.0 mg.
Phenylephrine hydrochloride	5.0 mg.
Phenyltoloxamine citrate	7.5 mg.
Chlorpheniramine maleate	2.5 mg.

Each pediatric formulation contains the following ingredients:	Pediatric Syrup each 5 ml. contains:	Pediatric Drops each 1-ml. dropper contains:
Phenylpropanolamine hydrochloride	5.0 mg.	5.0 mg.
Phenylephrine hydrochloride	1.25 mg.	1.25 mg.
Phenyltoloxamine citrate	2.0 mg.	2.0 mg.
Chlorpheniramine maleate	0.5 mg.	0.5 mg.

ACTIONS: Naldecon is useful for the relief of nasal congestion associated with pollen allergy and minor infections of the upper respiratory tract (the common cold, nasopharyngitis, acute and chronic sinusitis). Naldecon tablets are compounded with half of each ingredient in the outer layer for immediate action and the remainder in the slowly disintegrating core for a sustained effect.

The actions and uses of individual ingredients in the formulation are as follows:

Phenylpropanolamine Hydrochloride

Phenylpropanolamine hydrochloride[1] acts similarly to ephedrine. It is effective orally for the symptomatic control of allergic manifestations, such as perennial hay fever and bronchial asthma. Its action is more prolonged than that of ephedrine, and it is not so apt to produce anxiety complex as is ephedrine.

Phenylephrine Hydrochloride

Phenylephrine hydrochloride[2] is a more powerful vasoconstrictor than synephrine tartrate. When administered orally, it is a vasopressor and relatively nontoxic. The pressor and anti-allergic effects of the drug are produced by oral administration. Therefore, this route may be employed in the treatment of orthostatic hypotension and allergic disorders. The comparatively larger doses required for effective oral treatment are only rarely accompanied by mild gastrointestinal symptoms. These may be avoided by administering the drug after meals.

Phenyltoloxamine Citrate

Phenyltoloxamine citrate[3] is a β-dimethylaminoethyl ether of orthobenzylphenol; as such it belongs to the group of antihistaminics exhibiting the aminoalkyl ether structure. The incidence of side effects is low; at recommended doses, soporific effects occur in less than 7% of patients.

Chlorpheniramine Maleate

Chlorpheniramine maleate[4] has good therapeutic efficacy and lov incidence of side effects. It is comparable in therapeutic efficacy t other antihistaminics although administered in very low dosage.

INDICATIONS: Relief of distressing symptoms of colds and othe upper respiratory infections, acute and chronic sinusitis, hay fever and other pollen allergies:

Rhinorrhea	Lacrimation
Postnasal drip	Sneezing
Nasal congestion	Itching of eyes and nose
Sinus congestion	Head stuffiness

CONTRAINDICATIONS: Sensitivity to any of the ingredients.

PRECAUTIONS: This preparation may cause drowsiness. The patient should be cautioned against engaging in operations requiring alertness such as driving an automobile, operating machinery, etc. Do not exceed the recommended dose unless directed by a physician. Individuals with high blood pressure, heart disease, diabetes mellitus, thyroid disease, glaucoma, peripheral vascular disease or prostatic hypertrophy should use only as directed by a physician.

DOSAGE: This chart represents single dosages for the products listed below. Usual dosage schedule for Naldecon Pediatric Drops, Naldecon Pediatric Syrup and Naldecon Syrup is every 3 to 4 hours, not to exceed four doses in a 24-hour period. For sustained-action Naldecon Tablets, doses should be administered on arising, in midafternoon, and at bedtime.

Single Dosage for...	Pediatric Drops	Pediatric Syrup	Syrup	Tablets
3 to 6 months	1/4 ml.			
6 to 12 months	1/2 ml.	1/2 teaspoonful		
1 to 6 years	1 ml.	1 teaspoonful		
6 to 12 years		2 teaspoonfuls	1/2 teaspoonful	1/2 tablet
over 12 years			1 teaspoonful	1 tablet

How Supplied

CYCLAPEN® (cyclacillin) tablets:
250 mg scored tablets
500 mg scored tablets

Indications

Cyclapen® (cyclacillin) has less in vitro activity than other drugs in the ampicillin class of antibiotics and its use should be confined to the indications listed below.

Cyclapen® is indicated for the treatment of the following infections:

RESPIRATORY TRACT

Tonsillitis and pharyngitis caused by Group A beta-hemolytic streptococci

Bronchitis and pneumonia caused by *S. pneumoniae* (formerly *D. pneumoniae*)

Otitis Media caused by *S. pneumoniae* (formerly *D. pneumoniae*) and *H. influenzae*

Acute exacerbation of chronic bronchitis caused by *H. influenzae**

*Though clinical improvement has been shown, bacteriologic cures cannot be expected in all patients with chronic respiratory disease due to *H. influenzae*.

SKIN AND SKIN STRUCTURES (integumentary) infections caused by Group A beta-hemolytic streptococci and staphylococci, non-penicillinase producers.

URINARY TRACT INFECTIONS caused by *E. coli* and *P. mirabilis*. (This drug should not be used in any infections caused by *E. coli* and *P. mirabilis* other than urinary tract infections.)

NOTE: Cultures and susceptibility tests should be performed initially and during treatment to monitor the effectiveness of therapy and the susceptibility of bacteria. Therapy may be instituted prior to the results of sensitivity testing.

Contraindications

The use of this drug is contraindicated in individuals with a history of an allergic reaction to penicillins.

Warnings

CYCLACILLIN SHOULD ONLY BE PRESCRIBED FOR THE INDICATIONS LISTED IN THIS INSERT.

CYCLACILLIN HAS LESS *IN VITRO* ACTIVITY THAN OTHER DRUGS OF THE AMPICILLIN CLASS ANTIBIOTICS. HOWEVER, CLINICAL TRIALS HAVE DEMONSTRATED THAT IT IS EFFICACIOUS FOR THE RECOMMENDED INDICATIONS.

SERIOUS AND OCCASIONAL FATAL HYPERSENSITIVITY (ANAPHYLACTOID) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING PENICILLIN.

ALTHOUGH ANAPHYLAXIS IS MORE FREQUENT FOLLOWING PARENTERAL ADMINISTRATION, IT HAS OCCURRED IN PATIENTS ON ORAL PENICILLINS. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS. THERE ARE REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY REACTIONS WHO EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH A CEPHALOSPORIN. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE ABOUT PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, THE DRUG SHOULD BE DISCONTINUED AND APPROPRIATE THERAPY SHOULD BE INITIATED. SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN, INTRAVENOUS STEROIDS, AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

Precautions

Prolonged use of antibiotics may promote the overgrowth of nonsusceptible organisms. If superinfection occurs during therapy, appropriate measures should be taken.

PREGNANCY: Pregnancy Category B. Reproduction studies have been performed in mice and rats at doses up to ten times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cyclacillin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

NURSING MOTHERS: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when cyclacillin is administered to a nursing woman.

Adverse Reactions

The oral administration of cyclacillin is generally well tolerated.

As with other penicillins, untoward reactions of the sensitivity phenomena are likely to occur, particularly in individuals who have previously demonstrated hypersensitivity to penicillins or in those with a history of allergy, asth fever, or urticaria.

The following adverse reactions have been reported with the use of cy diarrhea (in approximately 1 out of 20 patients treated), nausea and v (in approximately 1 in 50), and skin rash (in approxmately 1 in 60). instances of headache, dizziness, abdominal pain, vaginitis, and urtica been reported. (See WARNINGS)

Other less frequent adverse reactions which may occur and that ha reported during therapy with other penicillins are: anemia, thrombocy thrombocytopenic purpura, leukopenia, neutropenia and eosinophilia reactions are usually reversible on discontinuation of therapy.

As with other semisynthetic penicillins, SGOT elevations have been re

Dosage and Administration

INFECTION*	ADULTS	CHILDREN
		Dosage should not in a dose higher th for adults.
Respiratory Tract		
Tonsillitis & Pharyngitis**	250 mg q.i.d. in equally spaced doses	body weight <20 lbs) 125 mg q.i equally spaced dos body weight >20 lbs) 250 mg q.i equally spaced dos
Bronchitis and Pneumonia		
Mild or Moderate Infections	250 mg q.i.d. in equally spaced doses	50 mg/kg/day q. equally spaced dos
Chronic Infections	500 mg q.i.d. in equally spaced doses	100 mg/kg/day q equally spaced dos
Otitis Media	250 mg to 500 mg q.i.d. in equally spaced doses depending on severity	50 to 100 mg/kg/ equally spaced dos pending on severity
Skin & Skin Structures	250 mg to 500 mg q.i.d. in equally spaced doses depending on severity	50 to 100 mg/kg/ equally spaced dos pending on severity
Urinary Tract	500 mg q.i.d. in equally spaced doses	100 mg/kg/day in e spaced doses.

*As with antibiotic therapy generally, treatment should be continued minimum of 48 to 72 hours after the patient becomes asymptomatic c evidence of bacterial eradication has been obtained.

**In infections caused by Group A beta-hemolytic streptococci, a minim 10 days of treatment is recommended to guard against the risk of rhei fever or glomerulonephritis.

In the treatment of chronic urinary tract infection, frequent bacteriolog clinical appraisal is necessary during therapy and may be required for s months afterwards.

Persistent infection may require treatment for several weeks.

Cyclacillin is not indicated in children under 2 months of age.

Patients with Renal Failure

Based on a dosage of 500 mg q.i.d., the following adjustment in d interval is recommended:

Patients with a creatinine clearance of >50 ml/min need n age interval adjustment.

Patients with a creatinine clearance of 30-50 ml/min should recei doses every 12 hours.

Patients with a creatinine clearance of between 15-30 ml/min receive full doses every 18 hours.

Patients with a creatinine clearance of between 10-15 ml/min receive full doses every 24 hours.

In patients with a creatinine clearance of ≤10 ml/mi serum creatinine values of ≥ 10 mg %, serum cyclacillin levels are r mended to determine both subsequent dosage and frequency.

The Critical Academic Mass

Intuition suggests that increasing departmental size might affect individual research productivity by enhancing opportunities to share ideas, responsibilities, and facilities. If so, the effect could either extend indefinitely (ie, "the bigger the better") or reach a plateau that indicates the point of maximum profitable interaction. In the United States, pediatric full-time faculty rosters presently range from three to 141, according to data provided by 116 department chairmen. A test of these concepts thus requires only a reasonable, quantitative estimate of productivity. We chose to count publications and presentations at the annual meetings of the Society for Pediatric Research and the American Pediatric Society (APS/SPR). Forty-eight journals were searched for articles published between July 1, 1976 and June 30, 1978 that originated from the 116 departments studied, and the programs of the 1977 and 1978 APS/SPR meetings were scanned for articles accepted for presentation. The journals selected included four that deal with pediatrics *(The American Journal of Diseases of Children, The Journal of Pediatrics, Pediatrics,* and *Pediatric Research)*, four that include both pediatric and adult medical research *(The Journal of Clinical Investigation, The Journal of Laboratory and Clinical Medicine, The New England Journal of Medicine,* and *Metabolism)*, *Science*, and 39 subspecialty journals. All articles from these sources were assigned to the departments with which their authors were associated. Some were credited to more than one department. Each list of departmental publications was divided by the number of full-time faculty; the result was designated as the departmental per capita productivity index (PI). Separate indices were calculated for general and subspecialty papers. The sample comprised a total of 4,198 items: 687 presentations, 1,660 articles in general research journals, and 1,851 articles in subspecialty journals.

Per capita productivity indices so derived are clearly different from those that would result from counting individual bibliographies within each department. The latter figures, however, would exceed the total number of publications because of the phenomenon of multiple authorship. A random sample of 100 papers gave an average of 3.6 (± 0.23) authors per paper; the summation of individual bibliographies would, therefore, suggest a total research output several times larger than life. An unfortunate aspect of this enumerative approach is the absence of qualitative evaluation. We hope that the efforts of editors, reviewers, and program chairmen, together with the large sample size, may have engendered a reasonable correspondence between quality and quantity. The limitation of the analysis to American departments, publications, and meetings was dictated by available clerical resources.

In research as well as in teaching and patient care, major contributions are made by those who hold qualified or "clinical" appointments. However, the time invested and the responsibilities assumed by such faculty members are so extremely variable that it seemed impractical to include them in the rosters on which this study was based.

The Table gives the results. The median departmental size was 30 members. Both general and subspecialty indices were much greater in departments with 30 or more full-time members. The difference was more noticeable for subspecialty than for general items. Above and below the median, there was no correspondence between departmental roster and PI. Nine departments had PIs of 2.0 or more; these were evenly distributed without relationship to size. They were (with rosters in parentheses): University of Vermont (seven), Penn State (14), University of Illinois (21), State University of New York, Upstate Medical Center (24), Yale (44), Washington University (46), University of California, San Francisco (52), University of Washington (60), and Harvard (141). Penn State and Harvard had PIs of 3.0.

Insofar as these results accurately describe productivity, the advantage of increasing departmental size appears to be reached when the roster is 30. Departments larger than this have larger total research outputs, of course, but no greater per capita efficiency. Evidently there is a limit to the amount of profitable interaction

Per Capita Productivity (PI) Related to Department Size

Roster Size (n)	PI, General (SE)	PI, Specialty (SE)	PI, Total (SE)	PI > 2.0
<30(57)	0.37(0.07)	0.20(0.03)	0.57(0.09)	4
>30(59)	0.58(0.05)*	0.45(0.04)†	1.03(0.08)†	5

*$P < .02$.
†$P < .001$.

between any one person and his colleagues. Responsibilities for patient care, teaching, administration, and advocacy might be lightened in larger departments; if so, any enhancement of research activity thus engendered apparently also reaches a plateau at 30. The phenomenon of extremely high productivity by some persons and small groups of investigators is well known and would be expected to introduce wide variability about the means shown in the Table; such is indeed the case. For statistical purposes, standard errors are given; the standard deviations (standard error $\times \sqrt{n}$) are relatively large, and approximate the means themselves. The wide distribution of PIs greater than 2 shows that exceptionally productive persons and groups are capable of overcoming the statistically significant effect of departmental size.

Patient care, teaching, and advocacy are equally important functions not susceptible to the simple quantitation offered here for research publications. If there is a critical mass for these activities, its definition will require the development and application of evaluative techniques not presently available.

Commentary on Immunization

Schedules for immunization against childhood infections have been issued periodically by select committees from the American Academy of Pediatrics and the Public Health Service. These schedules are especially appropriate for public health clinics, but the private physician may have reasons of his own to set up alternative patterns.

In *The Hazards of Immunization*, Wilson[1(p2)] defended freedom to oppose majority opinions and believed that long-adopted practices should periodically be critically scrutinized "lest the accumulated weight of precedent is allowed to obscure the need for their discontinuance."

Immunizations have greatly decreased the incidence of several common diseases in childhood; there is the possibility that some have only been deferred to adult years. The effectiveness of each agent cannot be compared directly with others, nor can any new agent be instantly accepted because of its resemblance to one that has been proved effective. Moreover, no vaccine should be inviolate of scrutiny and reevaluation.

Smallpox vaccine, the progenitor of live virus vaccines (LVVs), has the incomparable advantage that the resultant vaccine vesicle demonstrates the establishment of the benign protective infection. This is not true of current LVV, where resistance is demonstrated only by extensive experience or serological tests. One may be encouraged to believe that LVV agents should rival the duration and effectiveness produced by actual disease, but even the immunity that follows smallpox vaccination is not invariably prolonged; revaccination is required after one to three years, and mild forms of the disease may occur later on.

The conquest of diphtheria was accelerated by the discovery that horses could be immunized with modified toxin and that their blood serum could be used for prevention and treatment of the disease. This potent antitoxin was suspected to be useful against other infections although this proved to be untrue. An antitoxin against many other infections was anticipated but was not accomplished except to a limited extent. The treatment of diphtheria by antitoxin led to the use of modified toxin for childhood immunization.

The Schick test was first designed to demonstrate the adequacy of antitoxin at a time when it was customary to give daily doses of antitoxin in treatment. Later, this test served to demonstrate successful immunization. The Schick test has now been abandoned, which is unfortunate because it not only demonstrates the immunity of the patient given toxoid but also demonstrates his ability to respond to an antigenic stimulus.

Wallgren[2] stated that the presence of transplacental diphtheria antibodies interferes with the antibody response to toxoid. This is somewhat erroneous since booster injections given when antitoxin is present will cause a great increase in antitoxin levels, but it is possible that administration of toxoid later than extremely early in infancy might encourage a more durable immunity. However, immunization in early infancy is chosen to select the most accessible time to the patient.

Live virus vaccines, as in smallpox, succeed only to the extent that they produce subclinical infection. Immunization must usually be deferred until the disappearance of transplacental antibodies that could interfere.

POLIOMYELITIS VACCINE

Live virus poliomyelitis vaccine seems to be an exception for oral poliovirus vaccine (OPV) (Sabin live virus) is usually given at 2 or 3 months of age along with diphtheria and tetanus toxoids in combination with inactivated pertussis vaccine (DTP).

A recent observation suggests that OPV and DTP should not be given coincidentally. Four cases occurred in Britain[3] in which DTP and OPV given at the same time were followed by paralysis in 14 to 17 days. In all four, the extremity injected with DTP was the site of paralysis; in two, it was also accompanied by weakness elsewhere. Paralysis follows OPV only once in 2 to 5 million doses, but is it logical to combine it with another vaccine that is known to be a provocative agent? During poliomyelitis epidemics, it was observed that paralysis seemed to be precipitated by the injection of DTP, and weakness usually occurred in the extremity injected with DTP. With the prevailing immune protection of the population, it might be appropriate to defer OPV to 6 or 8 months of age instead of insisting on combining it with DTP in early infancy, avoiding a coincidental provocative agent.

INACTIVATED POLIOVIRUS VACCINE (IPV)

Inactivated poliovirus vaccine (Salk) does not produce subclinical infection, and transplacental antibodies do not interfere with the immune response. Salk and Salk[4] have stated that paralysis because of OPV now exceeds that caused by wild virus. Although this may be true, the numbers are extremely small: seven cases of poliomyelitis were reported in 1978, five of which were associated with OPV (MP Pollack, MD, written communication, May 9, 1979). When Salk's IPV was introduced in 1955, more than 100 paralytic cases were found to be due to the presence of live virus. Although the number of paralytic cases in the United States decreased after the introduction of IPV in the years 1957 to 1959, Wallgren[2] stated that a coincidental decline also occurred in Sweden where the vaccine was not yet used. Currently, it is used in Sweden with apparently good effect. In contrast to OPV, IPV requires repeated boosters, is more difficult to administer, does not afford as great a degree of herd immunity, and cannot be used for containment of an epidemic.

PERTUSSIS VACCINE

Pertussis vaccine was introduced about 1936; however, since at least 1900, there has been a steady decrease in mortality from this disease. With the advent of this vaccine, the decline has continued but is now piously attributed to vaccination. Mortality is probably the best statistical evidence of actual occurrence because morbidity is not so well reported. This continuous decline in mortality may be due to many factors, including better protection from exposure, improved nutrition, or, as occurs with many pathogens, a diminished virulence of the organism.

Frequent objections to the use of pertussis vaccine began to appear in the British literature about 1974. Stewart[5] has been a vociferous opponent and stated that DTP has little protective effect against whooping cough and causes innumerable adverse reactions that constitute a substantial risk. The risks are convincingly attributed to the pertussis component.[1(p263),6]

These opinions led to an editorial in *Lancet*[7] and a succinct review in the *New England Journal of Medicine*.[8] In the United States, there has been less concern about pertussis vaccine although severe adverse reactions were reported as early as 1948.[9] Barkin and Pichichero[10] in a review of 1,232 patients found a notable incidence of reactions although without the convulsions and encephalopathy that had been noted in more extensive studies.[11-13] In both Britain and the United States, public health authorities have moved furiously in defense of the vaccine. The British Joint Committee on Vaccination and Immunisation has had a survey under way since 1976 (unpublished data, September 1977) to determine the frequency of complications, but it is their unanimous opinion that the vaccine's use should be continued.

Edsall[14] commented that alarm over the publicity of sequellae in Britain has resulted not only in the decreased immunization against pertussis but has also regrettably interfered with the acceptance of other vaccines. He believed that these alarmist views have not been supported by facts and that the lack of acceptance of vaccination has been accompanied by an increase in the incidence of whooping cough. He did agree that an entirely different vaccine with less toxicity and more dependable protective effect is desirable.

Currently, a great increase in whooping cough has been reported in Britain, after opposition to vaccine and public rejection (about 1974). If the present epidemic is due to vaccine nonuse, this should be evidenced in children younger than 4 to 5 years of age and best indicated by mortality that is greatest in this age group. Such data together with morbidity in older children might defend the vaccine in regard to its effectiveness and support its worth.

There may be some reluctance to report reactions for fear of legal reprisals. The lack of reliable data about the incidence and severity of reactions might be compared with the meticulous surveillance of OPV since its introduction. A calculated risk factor of 1/4 or 5 million doses is believed to be acceptable with OPV. This is much less than the anecdotal estimates of severe reactions because of pertussis vaccine.

PERTUSSIS VACCINE UNIQUE

This vaccine is unique in that it is the only current vaccine consisting of a suspension of killed bacteria that is credited with effective and prolonged immunity. Similar vaccines consisting of killed bacterial suspensions are notoriously less dependable, less accepted, and require frequent boosters, eg, typhoid, plague, cholera, paratyphoid (which has been abandoned). Pertussis vaccine is a poor antigen so that the agglutination response may not measure its true protective value. It is impossible to compare the usefulness and safety of this vaccine with those of such antigenicity as the toxoids of diphtheria and tetanus.

If pertussis vaccine were proposed now for initial approval, it is questionable whether it would be endorsed; for that matter, Jenner would certainly have difficulty in receiving initial approval of his vaccine! It would be a

LIBRARY

shattering proposal that pertussis vaccine be impetuously abandoned. One need neither go this far nor assert that it has no beneficial effect. However, studies are in order both here and abroad for careful surveillance of risk and effectiveness; there may be differences in populations and in vaccines. A vaccine with less toxicity and more dependable protective effect has long been sought, and the search should continue.

MEASLES VACCINE

Inactivated measles virus vaccine was considered appropriate when it was introduced but was a near disaster. The effectiveness of attenuated live virus measles vaccine has been conclusively demonstrated, and this produces a benign infection that provokes long-standing immunity. Transplacental antibodies interfere, for measles virus is exquisitely sensitive to extremely small amounts of antibody. Thus, it is appropriately deferred until 15 months of age when all transplacental antibodies have disappeared.

RUBELLA AND MUMPS VACCINE

Rubella and mumps vaccine, used for less than ten years, have not been completely studied regarding their present and remote value. Rubella is a common, mild disease of childhood with few important complications; epidemics recur about every seven years, with the result that about 85% of adults are immune. The only major concern is infection during pregnancy, which might occur among the 15% nonimmune female population, because of the well-known devastating effects on the fetus. Immunization of both boys and girls at 15 months of age is officially recommended in the United States and is frequently required before first school attendance. A somewhat unrealistic hope is that herd immunity of both boys and girls will protect their mothers who might be susceptible and pregnant. An important and thus far unanswered question is whether immunization at 15 months of age will protect girls when they reach their childbearing years or if this immunity will lapse, as suggested by Horstmann et al,[15] who agreed with other authorities that the latest vaccine (RA27/3) is much better than previous vaccines.[16] Revaccination of girls at 11 to 12 years might be useful but is unlikely to be effectively carried out. But why not adopt the British scheme of vaccinating only the girls during early adolescence, with greater assurance of their immunity at childbearing age?

Mumps immunization, a latecomer, is advocated for both boys and girls. Complications in childhood are rare and risks are so minimal that there is little reason why all children should be immunized at 15 months, although some states require it before first school attendance. The CNS symptoms often reported as meningoencephalitis usually consist only of benign meningitis, which occurs in at least 50% of all mumps cases and probably occurs much more frequently than it is diagnosed[17]; Postinfectious encephalitis, a serious disease, is extremely rare (1/6,000). Deafness, frequently stated as a risk of mumps, occurs rarely (1/15,000) and is usually unilateral.[17] Orchitis practically never occurs before adult years, but it is much dreaded by men because of its painful course and the overstated belief that it will induce impotence or sterility. However, it is an open question whether vaccination at 15 months will protect the boy during his adult years. Would it not be more reasonable to immunize only boys during early puberty?

Probably the greatest reason for acceptance of rubella and mumps immunization is that they can be given in combination with measles (MMR), thus avoiding frequent patient visits. This, too, appeals to public health clinics, but there are other good reasons for frequent visits to the pediatrician during preschool years.

It is impossible to extrapolate from successful vaccination against diphtheria, tetanus, poliomyelitis, and measles to some other vaccines in common use or to predict the success of each newly developed one. They are not the answer to every disease, and their benefits and risks require careful evaluation. To equate unnecessary and perhaps frivolous immunizations with those of indisputable value is to denigrate those that are useful and to discourage public acceptance of all vaccines. The untoward experiences with inactivated measles vaccine and the swine influenza episode have not enhanced public confidence in routine immunization. Vaccinations should be divided carefully into those that are successful and necessary (poliovirus, diphtheria, tetanus, and measles) so as to be almost obligatory and those others that parents or physicians may select.

Impact of Mass Media on Adolescent Sexual Behavior

The Chicken or the Egg?

Although adolescent sexual behavior has become a focal point for debate among family members, educators, and health providers, the percent of young people who have their first intercourse experience in adolescence has not increased dramatically in the past decade.[1] The mass media has reflected the increased awareness of adolescent sexual behavior. One important issue that has arisen is whether certain of the attitudes and behaviors surrounding teenage sexuality are started by the media or if the media merely reflects the beliefs and attitudes already held in a community. By assessing the effect of the media on changing belief systems as well as on education of populations in such sexually related areas as venereal disease control, one could analyze the potential impact of publicity on adolescent sexual behavior.

The general conclusion of investigators in the field of mass communication is that the messages in the media merely reinforce attitudes that are already held.[2] Earl Ubell,[3] science editor for the Columbia Broadcasting System, has described the capability of the media as allowing people to become informed about the existence of an item or concept but not imparting sufficient details to lead to changes in behavior.

THE POTENTIAL ROLE OF MASS MEDIA

There are data to support the belief that mass media reporting may reinforce behavior that is already present but there is no evidence that mass media introduces the idea of premarital intercourse to young people. Motivation for a sexual behavior in a given adolescent is influenced by a series of factors. These include goals that make the action attractive or unattractive to an individual, as well as external and environmental influences that favor or oppose the behavior. If mass media techniques are to be adapted to health education to motivate adolescents to seek care for sexually related conditions, then factors which must be present include: (1) a belief that many individuals are susceptible to the illness (usually because of the presence of a sign or symptom); (2) a belief by individuals that the condition or disease is serious; and (3) a perception by individuals that they will benefit by changing behaviors.

Mass media can and should be used for adolescent health informational purposes. However, it must be appreciated that teenagers often engage in sexual behaviors for individual reasons that are not apt to be altered by an encounter with new information. Mass media can only be effective when there is little or no resistance to the adoption of new views.[3] When mass media do alter attitudes, the changes occur either in a small percent of the population at a given time or slowly over a long period. Commercial advertisers seek to influence the brand selection of sufficiently large numbers of consumers to make the advertising economically feasible. Such advertising techniques can reach individuals who are ready to buy an item but are searching for information about where to buy or selecting among similar products. Programs that try to modify a behavior rather than offering information should use surveys to test the "messages" and the potential impact of the programming. If such programs are to be used for health education, then they should not represent the only technique used in reaching the market population.

If mass media are to be used for the advancement of certain concepts or practices in preventive medicine, it is incumbent on the health provider to propose the desired content, potential outcome, and impact on public health. There would be little difficulty in enlisting members of the media to carry out such programming. Through the use of newspapers, magazines, radio, and television, an attempt should not be made to convince the public of ideas for which there is little scientific merit. If mass media is to be part of a campaign to inform adolescents about the problems of venereal disease, it is incumbent on public health workers to understand the limitations of the approach and to provide specific tasks for the media to perform. A venereal disease control program using mass media is suitable only if the social scientist demonstrates that the dissemination of information can play an important role in curbing the behavior that spreads the disease. The responsibility for designing such a program should rest in part with the health professional. The media can relay information to achieve the goals of alerting and informing an adolescent audience only after the other requirements are met by the health professional.[3]

INCREASING KNOWLEDGE AND CHANGE IN ATTITUDES OR BEHAVIOR

Transmitting information may increase knowledge but may have little effect on adolescent attitudes or sexual behavior. The concern on the part of adults regarding teenage sexuality is usually only focused on

the behavior. It is assumed that knowledge (or lack of it) plays a major role in adolescent sexual behavior.

However, recent studies of the effects of sex education courses on sexual attitudes and behaviors have indicated surprising results. A sex education course for eighth-grade adolescents had little influence on attitudes but did increase the tolerance for the sexual behavior of other students.[4] A study of the impact of sex education on a population of college students showed no relationship between those who participated in a course and their reported premarital sexual behavior.[5] There was also no difference in contraceptive behavior or in coital patterns between those college students who reported having had instruction in the use of birth control and those with no instruction. Similarly, no difference in behavior was noted between those who had different types of teachers or those who had courses in different years of school. Most surveys of the impact of sex education courses look only at changes in attitudes and rarely at changes in subsequent sexual behavior.[6]

There is certainly a major role for the media in education.[7] Although studies have been conducted that elucidate techniques that can be used to maximize learning capabilities, there remains a lack of thoughtful programming specifically designed for educational purposes. There is a need for continuing research on reactions to material by adolescents rather than relying solely on adult estimates of what the adolescents' reactions are likely to be. In an attempt to attract a large viewing, reading, or listening audience, media programmers often design the content of the show to be appealing to the least sophisticated viewers. Rapid-action sequences are frequently adopted rather than slower-paced scenes that might allow time for thoughtful reaction.[8]

Printed material requires separate comment. The comic book format, a style used in mass media literature, has been used by health educators because of the acceptability of visual material to many teenagers. This particular medium deemphasizes the format of uninterrupted paragraphs of written material. The "mediazation" of health educational materials has been well received by many teenagers, particularly when the graphic materials depict teenagers rather than adults and are representative of a cross-section of ages and ethnic groups.[9] The effort to incorporate practices used by mass media into health education is one of the major advances in health education. When the content is accurate and timely and is presented in a format that will have greater patient acceptability, it will certainly complement other efforts by health educators in transmitting factual, relevant material to the teenage consumer.

Some individuals maintain that the presence of sexually related materials in the press encourage overt sexual behavior, erode authority, and "encourage irresponsibility in others."[10] The current posture of the American Academy of Pediatrics regarding the violent content of television programs and excessive exposure of small children to advertising has been to try to limit both by influencing public policies through its youth advocacy role.[11] For the adolescent audience, concern has been expressed about the sex stereotyping that many television programs demonstrate as well as the unilateral presentation of views on such topics as teenage pregnancy, contraception, or abortion. However, it may be an error to extrapolate from the presumed effects of mass communication on the behavior of small children to the behavior of adolescents. Teenagers with normal personality development are less likely to be influenced in their behavior by external influences beyond their family, friends, and community than are younger children. To analyze the potential or real impact of the media on adolescent sexual behavior, an understanding of the development of adolescent decision making is necessary. The process of reasoning by which a teenager analyzes information, which results in a personal choice of a sexual behavior, has been linked with the individual's developmental stage of moral thinking.[12] The cognitive structure into which an adolescent places experiences is a major determinant of social behavior. The development of "abstract" thinking from "concrete" thinking is a normal cognitive milestone of midadolescence. Since discussion about decisions regarding sexuality have only recently been encouraged in our society, teenagers have little opportunity to practice high levels of moral reasoning. Adults often apply low levels of moral reasoning when discussing sexual decision making with teenagers.

It seems that choices regarding patterns of adolescent sexual behavior are independent of the effects of mass media. If adolescent sexual behavior is viewed as an "egg," then mass media can become the "nest" that nurtures the "egg" but cannot change its contents once the "egg" is formed.

Serum 1,25-Dihydroxyvitamin D Levels in Normal Children and in Vitamin D Disorders

Russell W. Chesney, MD; John F. Rosen, MD; Alan J. Hamstra, MS; Hector F. DeLuca, PhD

• Using a precise assay for 1,25-dihydroxyvitamin D in serum, the levels in 103 children, aged 13 months to 16 years, were found to be 43 ± 2 pg/mL (mean ± SE). This value is higher than reported values in adults and in neonates. Age-related changes in 1,25-dihydroxyvitamin D levels during childhood were also evident. Older children have significantly higher levels than children < 11 years, possibly indicating changes with puberty and the adolescent growth spurt. The values were significantly reduced in childhood uremia (13 ± 5 pg/mL), in hypoparathyroidism (16 ± 1 pg/mL), and in children with Fanconi's syndrome. Treatment with oral calcitriol in these three groups of patients led to increased serum levels.

***(Am J Dis Child* 134:135-139, 1980)**

Vitamin D requires two separate hydroxylations, first at carbon 25 occurring in the liver and later at carbon 1 in the kidney, to yield the biologically active metabolite, 1,25-dihydroxyvitamin D (1,25-$(OH)_2$D). This metabolite has notable antirachitic activity and stimulates the intestinal absorption of calcium and phosphorus.[1] Since this compound also leads to the release of calcium and phosphorus from bone,[2] its major biological role may be the maintenance of normal plasma concentrations of these divalent minerals. In children, disorders of bone mineralization may be related, in part, to decreased serum levels of 1,25-$(OH)_2$D, particularly as the rapid turnover of bone and growth demands of childhood requires net positive calcium and phosphorus balance.[3] The development of a highly sensitive and precise method of determining the serum levels of 1,25-$(OH)_2$D[4,5] permits direct measurements of this metabolite in children with disorders of calcium and phosphorus metabolism.

See p 140.

This study examines the concentrations of 1,25-$(OH)_2$D in normal children according to age, and it compares these values to previously published data in neonates and adults.[5,6] Comparisons of normal values with those found in children with hypoparathyroidism, uremic osteodystrophy, and Fanconi's syndrome were also made.

MATERIALS AND METHODS

An extra 7-mL aliquot of blood was removed from children undergoing venipuncture for routine laboratory studies prior to elective surgery (tonsillectomy, herniorrhaphy, or strabismus repair). These children, aged 13 months to 16 years, were healthy and remained anonymous; hence, they could not be further identified. Informed consent was obtained from the parents of these control subjects, using a protocol approved by the Human Subjects Committees in both Madison, Wis, and New York. Samples were obtained in each month of the year. Serum was stored at −20 °C until analyzed, and samples sent from New York were shipped in dry ice and were received in the frozen state. Samples were also obtained from patients with the following disorders: infantile nephropathic cystinosis, autosomal dominant Fanconi's syndrome,[7] Lowe's syndrome, idiopathic hypoparathyroidism that was identified by absent or diminished parathyroid hormone (PTH) levels[8] (13 cases), and uremic osteodystrophy (nine cases). Samples were also obtained in several patients after therapy with oral calcitriol (1,25-$(OH)_2$D) for at least several weeks. These samples were taken at four to six hours after the preceding dose of calcitriol.

Serum levels of 1,25-$(OH)_2$D were measured by the method of Eisman et al.[4,5] This method involves a specific extraction procedure in methylene chloride and a competitive binding assay using intestinal cytosol from rachitic chicks. Assays were always performed in parallel with known

internal standards to confirm reproducibility of the assays. The precision of this assay is ±2 pg/mL. Recoveries were determined using internal standard 1,25-$(OH)_2$-[^{3}H]D as previously described.[4,5] The calcitriol used for therapy was administered as a single morning dose.

Statistical significance of differences between groups was determined by Student's t test. Correlation coefficients were calculated by the Pearson's product moment formula.

RESULTS

Serum 1,25-$(OH)_2$D Levels in Normal Children

Shown in Fig 1 are the levels of 1,25-$(OH)_2$D found in 103 healthy children. The mean value obtained in 71 children from Wisconsin was 44 ± 3 pg/mL (mean ± SE), which is not different from the level of 41 ± 3 pg/mL found in 32 children from New York City. The value found in 50 girls was 44 ± 3 pg/mL compared with 39 ± 4 pg/mL in 53 boys. The overall mean level in the 103 children was 43 ± 2 pg/mL, with a range of 11 to 111 pg/mL. The relationship between serum 1,25-$(OH)_2$D levels and age has a linear correlation coefficient of $r = .418$ ($P < .001$), indicating that these levels increase with age proceeding from chilhood into adolescence. No seasonal differences were apparent. The (±SE) values at various ages were as follows: 1 to 2 years, 35 ± 2 pg/mL (n = 7); 3 to 4 years, 35 ± 2 pg/mL (n = 17); 5 to 6 years, 37 ± 4 pg/mL (n + 20); 7 to 8 years, 41 ± 4 pg/mL (n = 19); 9 to 11 years, 42 ± 8 pg/mL (n = 11); and 12 to 16 years, 55 ± 2 pg/mL (n = 29). The value in 74 children less than 12 years of age was 38 ± 3 pg/mL, which is significantly lower than the value of 55 ± 2 pg/mL in adolescents between the ages of 12 and 16 years ($P < .001$).

These values in all the children and adolescents as a group were significantly higher than that of 29 ± 2 pg/mL[4,5] found in adults by using the same assay method ($P < .005$) (Fig 2). In addition, the value in all children was significantly higher ($P < .001$) than that reported in 28 cord blood samples from term neonates, namely, 21 ± 2 pg/mL.[6] Nonetheless, our values and those reported by Scriver et al[9] are not significantly different. Finally, the values found in children aged 11 years or less were not statistically different from the values found in adults by Eisman et al.[4,5] The values found in all children were slightly higher than those reported by Scriver et al[9] of 37 ± 12 pg/mL (mean ± SD), but they studied only 12 normal children in contrast to the 103 healthy children we used to determine the levels during childhood.

1,25-$(OH)_2$D Levels in Childhood Uremia

Nine uremic children, aged 2½ to 13 years, with serum creatinine values between 2.5 and 7.6 mg/dL, had a serum level of 13 ± 5 pg/mL, significantly lower than the value in healthy children ($P < .001$). Seven of these children had tubulointerstitial disease, and two had chronic glomerulonephritis (Table 1). The level found in 11 other children, aged 8 to 16 years, with chronic glomerulonephritis and a serum creatinine concentration between 0.8 to 2.4 mg/dL, was 46 ± 6 pg/dL, significantly higher than the value found in the uremic children ($P < .01$).

The reduction in serum levels of 1,25-$(OH)_2$D was comparable to those reported previously by us in fewer children[10] and in adult uremic subjects.[11,12] The range of values in these nine children was 0 to 39 pg/mL and eight of the values were less than 24 pg/mL (Fig 3). The single patient with a value of 39 pg/mL had posterior urethral valves, a serum creatinine concentration of 2.5 mg/dL, and a serum calcium level of 9.4 mg/dL, and the patient was being treated with 15,000 units of ergocalciferol daily. Nonetheless, this patient had radiologically proved renal osteodystrophy and a serum immunoreactive PTH

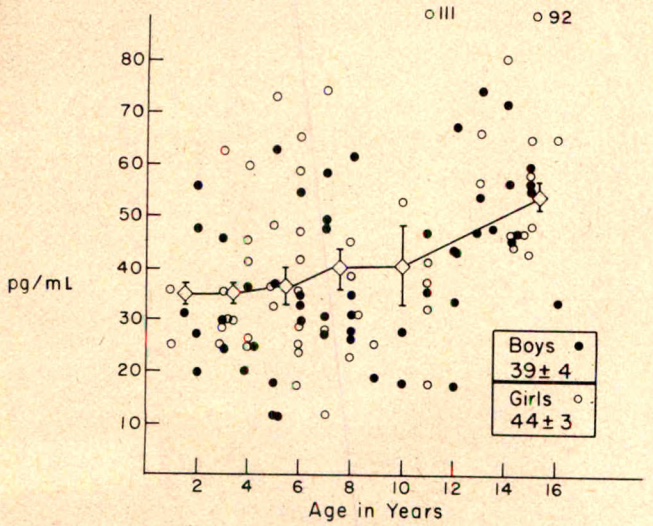

Fig 1.—Levels of 1,25-dihydroxyvitamin D in serum compared with age in children. Man (±SE) values for boys and girls are in inset. Mean (±SE) values (diamonds) are given for patients in varying age ranges. Numbers beside some points indicate serum levels.

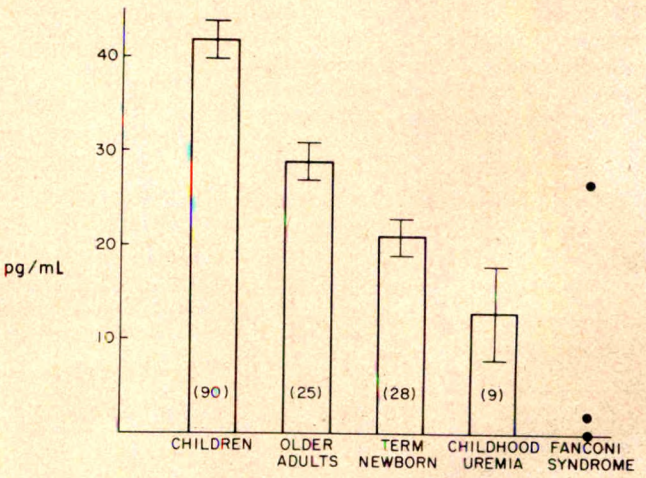

Fig 2.—Mean (±SE) levels of 1,25-dihydroxyvitamin D_3 in sera from various groups. Values for adults more than 25 years old[4,5] and for cord blood from neonates[6] were reported elsewhere. Numbers in parentheses indicate number of patients in each group. Values in healthy children are significantly higher than in other groups.

level of 660 μLEq/mL (normal, < 40 μLEq/mL). After therapy with calcitriol (0.026 μg/kg/24 hr) for five months, the serum level was found to be 78 pg/mL and the immunoreactive PTH level decreased to 230 μLEq/mL. The level of 1,25-$(OH)_2D$ in five patients measured four to six hours after oral therapy with calcitriol (0.015 to .0.050 μg/kg/24 hr) increased to 59 ± 10 pg/mL, a value similar to that of controls (Fig 3).

Levels in Idiopathic Hypoparathyroidism

Thirteen hypocalcemic patients, aged 1 to 14 years, with idiopathic hypoparathyroidism, two of whom had chronic mucocutaneous candidiasis, had a mean value of 16 ± 1 pg/mL, significantly different from control values ($P < .001$) (Table 2). After treatment with calcitriol for several weeks to months in seven patients, a oral dosage of 0.015 to 0.135 μg/kg/24 hr resulted in serum levels of 130 ± 18 pg/mL some four to six hours later and was associated with normocalcemia in six patients. The highest serum value, 295 pg/mL, was found in a previously described patient who had persistent hypocalcemia despite oral dosages of calcitriol of 0.135 μg/kg/24 hr.[13]

Values in Fanconi's Syndrome

The 1,25-$(OH)_2D$ levels in three patients with the typical urinary and bone findings of Fanconi's syndrome are shown (Fig 2). A 5½-year-old boy with nephropathic infantile cystinosis had an undetectable level while receiving 25,000 units of ergocalciferol (vitamin D_2) daily. The blood sample was taken when his serum creatinine concentration was 0.7 mg/dL and his CO_2 combining power was 18 mEq/L. The second patient, aged 14 years, had an autosomal dominant form of Fanconi's syndrome[7]; his serum creatinine level was 6.5 mg/dL and his CO_2 combining power was 18.5 mEq/L. While receiving 1.25 mg of dihydrotachysterol daily, the level of 1,25-$(OH)_2D$ was 2 pg/mL. On the administration of oral calcitriol (0.015 μg/kg/24 hr), the level was found to be 44 pg/mL when measured at both five and 11 months after therapy had begun. Both of these patients had

*Mean ± SE, 16 ± 1 pg/mL.

clinical and radiologic evidence of rickets prior to treatment with calcitriol. Serum calcium levels were 9.1 and 8.4 mg/dL, respectively, when the initial 1,25-$(OH)_2$D levels were determined.

A third patient, aged 15 years, had the typical features of Lowe's syndrome and a serum 1,25-$(OH)_2$D level of 29 pg/mL while receiving 50,000 units of ergocalciferol. This patient did not have rickets but did have osteoporosis. The serum CO_2 combining power was 23 mEq/L. This patient had a 1,25-$(OH)_2$D level well below the value of 55 ± 2 pg/mL (mean ± SE) found in 29 adolescents aged 12 to 16 years.

COMMENT

The finding of higher levels of 1,25-$(OH)_2$D in children between the ages of 1 and 16 years than in adults[4,5,14,15] or in cord blood[6] suggests that the concentrations of this active vitamin D metabolite reach a peak during childhood. The level found by Eisman et al[4,5] in normal adults was 29 ± 2 pg/mL, comparable to the values of 33 ± 6 pg/mL found by Haussler et al.[11,12] Of interest, these levels seem to be the highest during adolescence, a period of rapid growth and bone mineral accretion. Estrogen is known to augment 1α-hydroxylase activity and pregnancy can elevate 1,25-$(OH)_2$D levels.[16,17] Possibly, the increased values of 1,25-$(OH)_2$D are related to hormonal changes taking place during puberty and permit the greater intestinal mineral absorption needed for growth. Unfortunately, we have not established the normal levels for the first 12 months of life, the period of most rapid growth during life. Investigators using 1,25-$(OH)_2$D levels in adolescents should be aware of the higher levels in this age group.

It is of interest that the 1,25-$(OH)_2$D concentrations found in children in an urban environment with reduced sunlight exposure (New York City) are similar to those in children living in a rural setting (Wisconsin). The values were also similar regardless of the patient's sex or the season. The values in adolescents were higher in both locations. The value for 1,25-$(OH)_2$D in sera is approximately 0.1% to 0.2% of that reported for 25-hydroxyvitamin D (25-OH-D) and 1% of that for 24,25-dihydroxyvitamin D (24,25-$(OH)_2$D),[18] indicating the relative ratio of these respective compounds in children is 1000:100:1.

Uremia is known to impair the production of 1,25-$(OH)_2$D in man,[19] and the serum levels in uremic adults are low.[4,5,11,12] These patients, undergoing long-term hemodialysis, were anephric and had undetectable levels of 1,25-$(OH)_2$D. Our patients are children, totally ambulatory, whose conditions are managed by conventional therapy for chronic renal insufficiency, and they have an average serum creatinine clearance of 5.4 mg/dL. Nonetheless, the levels were substantially reduced in these nine children and were found to be in the normal range in the five patients sampled six hours after treatment with 0.015 to 0.05 μg/kg/24 hr of calcitriol.

Patients with hypoparathyroidism have absent or reduced levels of PTH and elevated serum (and intracellular) levels of phosphate. A reduction in circulating 1,25-$(OH)_2$D would be anticipated.[1] Accordingly, as reported by Rosen et al[8] and Kooh et al,[20] the levels of this metabolite are low. We find a reduction of similar extent to that found in uremia. However, in contrast to the situation in uremia, the serum levels increased from a mean of 16 to 130 pg/mL six hours after a roughly comparable oral dose. Rosen et al[8] further demonstrated that these values return to pretreatment levels after 24 hours. Whether there are differences in the pharmacokinetics of 1,25-$(OH)_2$D in patients with uremia vs patients with hypoparathyroidism remains unknown. Despite levels that were three times normal, these seven patients were not hypercalcemic. Indeed, one patient, previously reported by us[13] remained hypocalcemic in the face of high levels (295 pg/mL) after therapy with high doses of calcitriol (0.135 μg/kg/24 hr). Of interest is that our posttreatment values were higher than those reported in two patients with pseudohypoparathyroidism who had overt hypercalcemia at serum 1,25-$(OH)_2$D levels of 53 and 77 pg/mL.[21] These latter values were determined by using a different bioassay and, therefore, may not be entirely comparable.

The levels in three patients with Fanconi's syndrome were low, similar to those reported by Brewer et al[22] who studied the metabolites in plasma after 25-OH-[^{3}H]D administration. Although it is well recognized that hypophosphatemia resulting from reduced renal tubular phosphate reabsorption is important in the pathogenesis of bone disease, healing of rickets in Fanconi's syndrome can occur with large doses of vitamin D or with intensive alkali therapy.[23] Recent animal studies have suggested that systemic metabolic acidosis per se

impairs the conversion of 25-OH-D to 1,25-$(OH)_2$D.[14,15,24,25] Using the maleic acid model of Fanconi's syndrome, which results in systemic acidosis, the activity of 25-OH-D_3-1α-hydroxylase in rats was reduced despite a normal glomerular filtration rate.[15] Our two patients with subnormal serum CO_2 combining power values had extremely low 1,25-$(OH)_2$D levels, although one of these patients had renal insufficiency when the sample was obtained. The child with Lowe's syndrome had a level more than 2 SD below the value of 54 ± 11 pg/mL (mean ± SD) found in healthy 13- to 16-year olds. Further values from patients with Fanconi's syndrome would obviously be of interest.

This study demonstrates that the circulating levels of 1,25-$(OH)_2$D are higher in older than in younger children and further demonstrates that children with uremia, hypoparathyroidism, and Fanconi's syndrome have reduced serum levels of this active metabolite.

Supranormal 25-Hydroxyvitamin D and Subnormal 1,25-Dihydroxyvitamin D

Their Role in X-linked Hypophosphatemic Rickets

Russell W. Chesney, MD; Richard B. Mazess, PhD; Philip Rose; Alan J. Hamstra, MS; Hector F. DeLuca, PhD

• **Serum 25-hydroxyvitamin D (25-OH-D) and 1,25-dihydroxyvitamin D (1,25-$(OH)_2D$) and bone mineral content by the photon-absorption technique were determined in eight patients with X-linked hypophosphatemic rickets treated for at least 24 months with oral sodium phosphate and high-dosage ergocalciferol (vitamin D_2). Mean 25-OH-D_2 level was 129.5 ± 67.5 ng/mL (mean ± SD); the level of 25-OH-D_3 was 10.5 ± 5.8 ng/mL. These values were significantly higher than in normal subjects (total 25-OH-D mean of 27 ± 10 ng/mL). Serum 1,25-$(OH)_2D$ was 16.9 ± 8.5 pg/mL (mean ± SD) in the eight patients, significantly lower than 47 ± 16 pg/mL in 27 age-matched controls. Values indicative of significant demineralization were found in seven of the eight phosphate-treated patients, who had no radiologic evidence of rickets. These results suggest that any theory of the pathogenesis of this disorder must account for inappropriate renal vitamin D metabolism and for renal hyperphosphaturia. The failure of high-dosage oral phosphate and ergocalciferol to fully correct demineralization may suggest a role for calcitriol (1,25-$(OH)_2D_3$) as a therapeutic agent.**

(*Am J Dis Child* 134:140-143, 1980)

X-linked hypophosphatemic rickets is characterized by hyperphosphaturia despite severe hypophosphatemia, by normocalcemia, and by rickets unresponsive to therapy with doses of vitamin D that cure simple vitamin D deficiency. This condition, therefore, has sometimes been called vitamin D-resistant rickets.[1] The net tubular reabsorption of phosphate is decreased in all patients with this disorder.[2] Two completely opposing theories of the pathogenesis of this disorder have emerged since the first clinical description in 1937 by Albright et al.[3] Albright and co-workers ascribed the disorder to an abnormality of vitamin D metabolism that would result in intestinal calcium malabsorption, secondary hyperparathyroidism with hyperphosphaturia, and hypophosphatemia. However, the finding of normal or only slightly elevated plasma immunoreactive parathyroid hormone (iPTH) levels in untreated patients with this disorder[4,5] led to support for a second pathogenic mechanism. In this second hypothesis, hypophosphatemia was directly related to defective transport of the phosphate ion across the renal tubule and intestinal mucosa. This was viewed as an isolated transport defect that ultimately resulted in undermineralization of bone and in rickets.[6]

See p 135.

The original hypothesis required the existence of abnormalities of vitamin D metabolism to account for the intestinal calcium and phosphate malabsorption found in patients with this disorder.[7] However, the levels of 25-hydroxyvitamin D (25-OH-D) have been found to be normal in at least two separate studies.[8,9] Recently, Drezner and Haussler[10] have reported that the circulating levels of 1,25-dihydroxyvitamin D (1,25-$(OH)_2D$), the most active metabolite of vitamin D described to date, are normal in patients with this disorder. Nonetheless, these authors point out that a normal level is somewhat surprising since these patients are hypophosphatemic and presumably have reduced

renal tubular intracellular phosphate levels, a known stimulus to 1,25-$(OH)_2D$ production.[11] In contrast, Scriver et al[12] have recently reported that serum 1,25-$(OH)_2D$ levels were significantly subnormal in patients with hypophosphatemic rickets. Using a precise assay of 1,25-$(OH)_2D$, we have also examined the levels of this metabolite in eight patients with hypophosphatemic rickets.

Radiologic evidence of healing of rickets and improved growth velocity have been reported after the administration of several grams of oral phosphate given every four to five hours in addition to high-dose vitamin D (20 to 75×10^3 units per day).[13-15] Histologic evaluation of bone after this form of therapy has not been extensively reported, and it is not established that the therapeutic regimen of phosphate and high-dose vitamin D completely corrects the bone disease. Recently, Glorieux et al[16] have reported persistence of osteomalacia and widened osteoid seams in bone biopsy specimens from patients treated with ergocalciferol (vitamin D_2) and phosphate. Accordingly, we[17] have examined the bone mineral content (BMC) of our patients, whose conditions were treated with this therapeutic regimen, using the technique of direct photon absorptiometry and have compared these results with appropriate control values.

PATIENTS AND METHODS

The eight children (six girls and two boys), aged 2 to 13 years, had short stature (a height less than the third percentile), hypophosphatemia (<2.5 mg/dL), and radiologic evidence of rickets prior to treatment. A family history of hypophosphatemic rickets was found in five children, two of whom were siblings; and in each instance, the history was consistent with an X-linked inheritance pattern. The mothers of two other patients had fasting hypophosphatemia, 2.4 mg/dL and 2.3 mg/dL, respectively, but they were not short or bowed. The other child could be considered to have the sporadic form of the disease. None had aminoaciduria, glucosuria, or renal bicarbonate wasting. None of the patients had associated myopathy, and in each case, rickets was radiologically verified as improved after therapy. Prior to therapy, the serum iPTH level was in the normal range (less than 40 μLEq/mL).

Treatment consisted of oral sodium phosphate (Joulie's solution) given at 1.5 to 3.6 g daily in five divided doses[15] and ergocalciferol given at 20,000 to 75,000 units daily (0.5 to 1.875 mg). Each patient had been treated for at least 24 months with this regimen, with a resultant increase in height from less than the third percentile to between the tenth and 25th percentiles using growth standards of the National Center for Health Statistics.

Blood was obtained for vitamin D assay from control subjects who were undergoing elective surgery, including tonsillectomy, herniorrhaphy, or strabismus repair. Serum samples were obtained from these healthy children at different times during the year. Informed consent was obtained from the parents of these normal subjects according to a protocol approved by the Human Subjects Committee of the University of Wisconsin Center for Health Sciences, Madison.

Vitamin D metabolites were measured using specific binding assays after extraction of serum samples in methanol and methylene chloride and separation by fractionating column (Sephadex LH-20) chromatography. The vitamin D metabolites, 25-OH-D_2, 25-OH-D_3, 1,25-$(OH)_2D_2$ and 1,25-$(OH)_2D_3$ were separated by high-pressure liquid chromatography as described by Eisman et al.[18-20] The 25-hydroxymetabolites were measured by direct high-pressure liquid chromatography, and the 1,25-dihydroxyvitamin D levels were measured using the vitamin D-deficient chick intestinal cytosol protein.[18-20]

Absorptiometric determinations of BMC were measured by the use of a narrow beam of low-energy radiation from a monoenergetic radionuclide source (iodine 125 at 27.4 kiloelectron volts). The source and photon detector were moved across the radius and ulna of the nondominant arm as we have described elsewhere.[17,21] Changes in beam intensity are coupled to attenuation by bone mineral and the integrated attenuation pattern is proportional to the mass of mineral in the scan path. The BMC, bone width (BW) (proportional to the length of the scan path), and their ratio (BMC/BW) were ascertained in both forearm bones at a point one third of the forearm length proximal to the ulnar styloid. The radiation dose was less than 10 mrem (compared with the International Commission on Radiological Units maximal limb dose of 7,500 mrem). The precision of this method is within 2% to 3%, and these scans accurately indicate the ash weight of bone to within 1% to 3%.[22] The BMC, BW, and BMC/BW values obtained were compared with values obtained from more than 800 healthy age- and sex-matched controls, reported elsewhere.[17] Multiple regressions were calculated in each sex for the BMC of each bone using height, weight, age, and BW as independent variables. The SE of estimate was about 10%, so that a reduction of more than 20% in BMC or BMC/BW ratio indicated significant demineralization (or a change of >2SD).[17,21]

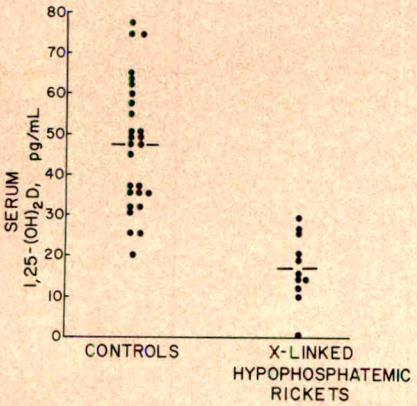
Serum iPTH was assayed as described elsewhere.[4] Statistical analysis was done by Student's t test.

RESULTS

Serum was obtained from patients three to four hours after their early morning dose of oral phosphate and ergocalciferol for the following values: serum calcium, magnesium, phosphorus, alkaline phosphatase activity, vitamin D metabolite levels, and iPTH levels. Simultaneous roentgenograms of knees and hands and photon absorptiometric measurements were also obtained. Height was measured using a fixed wall stadiometer.

Serum calcium was 9.42 ± 0.26 mg/dL (mean ± SD) in 11 measurements from the eight patients (normal range for our laboratory, 9.5 to 10.4 mg/dL). The serum phosphate concentration was 3.04 ± 0.46 mg/dL, in comparison with the normal range for children of this age of 3.5 to 5.8 mg/dL. The serum alkaline phosphatase value was 378 ± 217 IU/L, the normal in our laboratory being 280 IU/L or less. Serum magnesium value was normal. No rickets was observed. However, coarsened trabeculations and radiologic evidence of incomplete healing of rickets were noted in the two sisters; whereas other laboratory studies, including serum phosphorus levels of 2.8 mg/dL and 2.7 mg/dL, respectively, and alkaline phosphatase values of 756 IU/L and 864 IU/L, indicated poor compliance with the treatment regimen. These girls also had severe bowing of their legs.

Serum levels of iPTH were measured in five patients while receiving oral phosphate and ergocalciferol. Prior to receiving this therapeutic regimen, the serum iPTH levels were in the normal range (<40 μL Eq/mL) for each patient. The mean level for the five patients receiving therapy was 61.1 ± 13.9 μL Eq/mL, indicative of mild hyperparathyroidism.



Concentration of $1,25\text{-}(OH)_2D$ in serum. Concentration was measured in serum from 27 healthy, age-matched control subjects and from eight patients with hypophosphatemic rickets. Means in control subjects, 47 ± 16 pg/mL, and in patients, 16.9 ± 8.5 pg/mL, were significantly different from one another ($P < .001$).

The serum levels of 25-OH-D metabolites were substantially elevated, particularly 25-OH-D_2. The serum 25-OH-D_2 level was 129.5 ± 67.5 ng/mL (mean ± SD) and the 25-OH-D_3 level was 10.5 ± 5.8 ng/mL. The total 25-OH-D_2 and 25-OH-D_3 level of 140 ± 66 ng/mL ($n = 11$) was significantly higher than the value in 30 controls of 27 ± 10 ng/mL ($P < .001$). The combined, simultaneous levels of $1,25\text{-}(OH)_2D_2$ and $1,25\text{-}(OH)_2D_3$ are shown in the Figure in comparison with the levels of age-matched control subjects. The mean level of $1,25\text{-}(OH)_2D$ in the eight patients was 16.9 ± 8.5 pg/mL, significantly lower than the level in 27 healthy children of 47 ± 16 pg/mL (mean ± SD), $P < .001$. The values for controls shown in the Figure represent the values found in healthy children of the same age in years as the patients.

Nine measurements of photon absorptiometry were available when vitamin D metabolites were also obtained. Values indicative of significant demineralization (>−2SDs) using the BMC/BW ratio were found in seven of the eight patients; each of the same seven patients was demineralized when the BMC of either the radius or the ulna was examined. These hypophosphatemic patients had a reduction in BMC of minus 2 to 2.5SD in comparison with values of minus 3 to 4 SD found by us[17] in uremic subjects. Furthermore, the greatest reduction in BMC and BMC/BW ratio was found in the two children with poor treatment compliance.

COMMENT

In these patients with the typical features of X-linked hypophosphatemic rickets undergoing treatment with oral phosphate and high doses of ergocalciferol, the serum levels of 25-OH-D were greatly elevated, being as high as ten times normal. Nonetheless, there was evidence of a reduction in the conversion of 25-OH-D to $1,25\text{-}(OH)_2D$ in these patients since $1,25\text{-}(OH)_2D$ levels were substantially reduced. The concentrations of $1,25\text{-}(OH)_2D$ found in our patients were similar to those found by Scriver et al[12] using the same competitive binding assay in 14 patients. These authors found reduced levels in both treated and untreated patients. Therefore, the levels seem to be reduced in at least 22 different children with this disorder. Of importance is that these data come from two separate parts of North America, Wisconsin and Quebec, and thus indicate the same finding in different regions. The reports by Drezner and Haussler et al[10,23] of normal values of $1,25\text{-}(OH)_2D$ in hypophosphatemic patients is somewhat at variance with these results. Drezner and Haussler have reported values of 30 ± 8.4 pg/mL in ten patients aged 13 to 35 years. In addition, their patients were not treated with vitamin D or phosphate. They postulated that such therapy could have led to a reduction in circulating $1,25\text{-}(OH)_2D$ concentrations by inhibiting the activity of the 1α-hydroxylase enzyme. Nonetheless, from our own data for healthy normal subjects of ages 13 to 35 years (during adolescence and the young adult period), the mean plasma level of $1,25\text{-}(OH)_2D$ should be 50 ± 10 pg/mL. Accordingly, a serum level of 30 pg/mL is low for patients in this age group. The normal values given by Haussler et al,[23] 20 to 45 pg/mL, may not be from subjects of a comparable age.

Drezner and Haussler[10] have also made the point that normal plasma $1,25\text{-}(OH)_2D$ levels would be low in the face of severe hypophosphatemia. Indeed, these values should probably be elevated since a reduced intracellular phosphate level leads to increased $1,25\text{-}(OH)_2D$ synthesis.[11] It is of interest that our patients, with a mean serum phosphorus value of 3.04 ± 0.47 mg/dL, well below the normal range for age, have demonstrated reduced $1,25\text{-}(OH)_2D$ levels. However, the $1,25\text{-}(OH)_2D$ levels were obtained three to four hours after phosphate therapy, when phosphate levels are known to have decreased from the peak found after one to two hours.[15] It is thus difficult to fully know from the data at hand whether or not renal 1α-hydroxylase response is appropriate in treated patients with fluctuating serum phosphate concentrations. Nonetheless, the finding of Scriver et al[12] that both treated and untreated hypophosphatemic patients have reduced $1,25\text{-}(OH)_2D$ levels points to impaired 1α-hydroxylase activity at a variety of serum phosphate levels.

The level of serum calcium in our patients may have been low enough to cause elevated serum iPTH levels, another potent stimulus to the production of $1,25\text{-}(OH)_2D$.[24] We have measured iPTH values in five of these patients after the onset of therapy and have found that these values were about 50% higher than normal, probably related to the high oral phosphate intake.[15] Therefore, reduced $1,25\text{-}(OH)_2D$ levels found in these patients were present despite hypophosphatemia and elevated iPTH levels, known stimuli to $1,25\text{-}(OH)_2D$ synthesis.

The differences in $1,25\text{-}(OH)_2D$ levels reported to date may also reflect different patient groups with this disorder since it is recognized that this is a clinically heterogenous disorder.[1,3,12] Some patients have bone disease without overt rickets,[12] some have parathyroid adenomas,[3] and the genetics of this condition may be quite varied.[1,13] Within a given clinical subset of hypophosphatemic rickets, forms with varying vitamin D metabolite levels may prevail.

We have used the photon absorptiometric technique to demonstrate

that therapy with oral phosphate and high-dose ergocalciferol may not fully correct undermineralization of bone. Histologic evidence suggests that this form of treatment may not fully correct the osteoidosis of hypophosphatemia.[16,25] Our data would indicate that substantial demineralization is present after phosphate supplementation and thus supports the histologic data. This finding of demineralization after phosphate and ergocalciferol therapy could indicate that suboptimal levels of these two agents were used in treating these patients. However, serum phosphate levels were generally maintained at more than 3.5 mg/dL, and serum iPTH levels were elevated in five of the patients, indicative of excessive oral phosphate intake. In addition, Glorieux et al[25] have shown evidence of osteomalacia and widened osteoid seams using the same treatment regimen. Whether oral 1,25-$(OH)_2D$ treatment will correct this undermineralization, as has been suggested in a few patients,[25-27] awaits long-term critical evaluation. Certainly, our findings of reduced 1,25-$(OH)_2D$ levels suggests that trials of long-term replacement therapy with this vitamin D analog should be undertaken.

The finding of reduced 1,25-$(OH)_2D$ levels in patients with hypophosphatemic rickets is unexpected according to the two major pathogenetic theories about this condition. Albright's hypothesis states that hypophosphatemia follows secondary hyperparathyroidism.[1-3] The other hypothesis states that an isolated renal phosphate leak is primary.[2,6] In either instance, elevated 1,25-$(OH)_2D$ levels would be anticipated. Rasmussen and Anast[1] have recently postulated that a defect in the distal tubule could account for both the renal phosphate leak and the block in 1,25-$(OH)_2D$ synthesis, and in their hypothetical models, the renal tubule is supersensitive to the action of PTH as well. Our data would indicate that any theory of the pathogenesis of this disorder must account for hypophosphatemia with a renal phosphate leak and reduced 1,25-$(OH)_2D$ levels.

Laryngeal Mucous Gland Excess in Victims of Sudden Infant Death

B. Raymond Fink, MD, J. Bruce Beckwith, MD

• **Larynges from 13 victims of sudden infant death syndrome (SIDS) and from ten controls of comparable age were subjected to serial histological transverse section and examined for structural differences that bear on functional performance. The cross-sectional area of mucous glands in the vestibular fold, expressed as a percent of the total cross-sectional area of the fold was 19.52 ± 8.56 (mean ± SD in the SIDS specimens), and 12.56 ± 6.25 in the controls. The difference is statistically significant and suggests that excess mucous laryngeal secretion may be present in at least some cases of the syndrome.**

(*Am J Dis Child* 134:144-146, 1980)

The term sudden infant death syndrome (SIDS) is conventionally applied to a sudden and unexpected death in which a thorough postmortem examination fails to demonstrate inherently lethal pathology.[1] In recent years, at least one investigator has reported finding certain lesions, including thickened pulmonary vessel walls, that he attributes to chronic hypoxemia[2]; the small pulmonary arteries of cases of SIDS may have 1.6 times as much muscle as those of controls.[3] Some other observers, however, have been unable to confirm the findings.[4] A cause of recurrent hypoxemia is available in the long periods of apnea observed with quiet sleep (NREM sleep) in infants,[5] and such apnea episodes have been held responsible for "near misses."[6]

A history and signs of upper respiratory infection are common in SIDS victims, but are usually too mild to be the direct cause of death. However, Guilleminault et al[6] have shown that upper airway apnea occurs more frequently than usual in infants with such infections, and believe that this may trigger a fatal cardiac arrhythmia during a period of NREM sleep.

The results of a recent study in this laboratory stressed the importance of elastic elements in the reopening of the closed larynx[7] and led us to survey the histology of larynges from SIDS and non-SIDS deaths. In the course of examination of histological sections treated with elastic tissue stains, an apparent divergence was noted in the morphology of the mucous glandular tissue in the vestibular folds of the two groups. A morphometric sampling of this tissue was therefore undertaken and the results are as follow.

MATERIAL AND METHODS

The material consisted of the larynges from 13 victims of SIDS and ten infants who died from other causes and who served as controls. In each instance, permission to remove the larynx for study was obtained individually from the parents. Owing to the scarcity of control specimens in comparison to SIDS specimens, the SIDS larynges subjected to study were selected to compare as closely as possible with the ages of the controls. The selection was made prior to the histological examination of the specimens.

The complete larynx was fixed in 4% formaldehyde and embedded in paraffin. Serial transverse sections 10 μ thick were cut from the tissue between the top of the vestibular folds and the laryngeal sinus. Two sections, one from the craniad and one from the caudad region of the left vestibular fold, respectively at the minimum and maximum anteroposterior lengths of the saccule, were selected in each larynx, with the exception of specimen 75-11, for which tissue from only the caudad level was available and the sections came from the top and bottom of this piece. The selections were made by a technical assistant unaware of the nature of the survey, before staining with hematoxylin-eosin. Thus, the sections examined represent an unbiased selection of samples from each specimen. The sections were then coded by another assistant so that their source (SIDS or control) was unknown to the observer (B.R.F.). The entire set of 45 slides was assembled before measurements began.

The sections were examined in a binocular microscope at ×25 magnification. The cross-sectional area of the vestibular fold and of the mucous glands in the fold was measured with a micrometer grating subdivided into 100 squares of 0.01 sq mm, inserted in the left ocular. Grid squares half filled by mucous gland were counted as 1; squares less than half covered by mucous gland were counted as 0.

All soft tissue in the left vestibular fold, defined as the soft tissue medial to the thyroid cartilage and anterior to a line tangent to the posterior surface of the arytenoid cartilage, was included in the measurement. Each grid was counted twice, first horizontally and then vertically. The measurements agreed within 2% and were averaged.

The ratio of total number of grid squares occupied by mucus or by mucous gland tissue to the total number of grid squares occupied by the vestibular fold was calculated. Lymphoid tissue was excluded from the count of mucous tissue. For convenience, the ratio multiplied by 100 will be referred to as the mucous gland index. Thus, the mucous gland index was determined at two levels of the vestibular fold in each larynx, equivalent across the two groups.

RESULTS

The mucous gland indices calculated from the measurements are listed in the Table. The mean mucous gland index (± SD) for the 13 SIDS larynges was 19.52 ± 8.56. The average for the ten controls was 12.56 ± 6.25. The difference is significant statistically ($t = 3.00$; $P < .01$; two-tailed Student's t test), assuming both samples

*Mucous index is ratio of area of mucous glands to area of vestibular fold, ×100. Measurements were made at the top and bottom of the left vestibular fold of each larynx. For the 13 SIDS samples, mean ± SD was 19.52 ± 8.56 (t = 3.00, 21 df, $P < .01$ [two-tailed]).

†Mean ± SD was 12.56 ± 6.24 (n = 10).

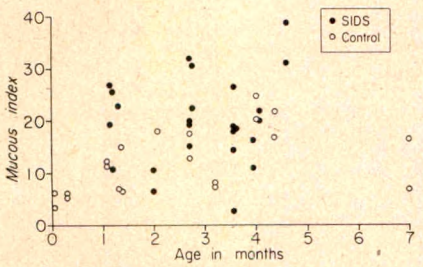

Fig 1.—Distribution of laryngeal mucous gland index in relation to age in victims of sudden infant death syndrome (SIDS) and in controls. Mucous gland index indicates the ratio of area of mucous glands to area of vestibular fold, times 100.

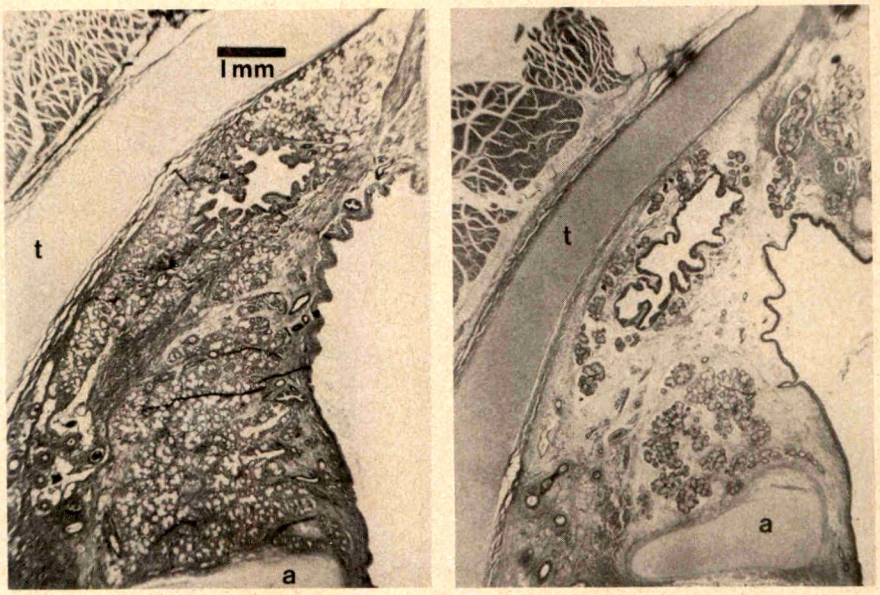

Fig 2.—Cross sections through the upper part of the left vestibular fold (hematoxylin-eosin, ×25); left, sudden infant death syndrome (SIDS); right, control. Point a indicates arytenoid cartilage; t, thyroid cartilage. Note apparent excess development of glandular acini in the SIDS specimen.

are drawn from normal distributions (Fig 1).

To test the significance of the data in the absence of an assumption concerning distribution, the nonparametric Mann-Whitney U test[8] was applied. On the H_1 hypothesis that the larynges from SIDS contained more mucous vestibular glands than the controls (two-tailed test), the calculated value of U was 147.5, the value of Z was −2.49, and the associated probability .0064. The H_1 hypothesis is therefore accepted.

Representative cross sections from a SIDS larynx (SIDS 643) and a control larynx (77.56) at the lower level of the vestibular fold are shown in Fig 2. The cells of the glandular acini were equally well defined in the two series. There was no suggestion of swelling or of inflammatory infiltration.

COMMENT

An exact inventory of the amount of mucous glandular tissue in the

larynx is not available. *Gray's Anatomy* states that mucous glands to the number of 60 or 70 open into the saccule.

The general topography of the mucous glands of the larynx was reviewed by Heiss.[9] He distinguished an anterior epiglottic, a middle or vestibular, and a posterior or interarytenoid group, and noted that the vestibular group is particularly well developed. Nassar and Bridger[10] suggested that, histologically, the glands are segregated into groups that are able to influence the spread of cancer, but these authors did not attempt to establish numerical measurements for the glandular densities. We found no information on this point, either in the adult or the infant, in the literature. In the present study, only the vestibular and epiglottic groups were counted, but corresponding regions of these groups were sampled in all specimens.

In our series, the SIDS victims ranged in age from 1 month and 3 days to 4 months and 17 days, and the controls from 1 day to 7 months. Great difficulty was experienced in obtaining permission for control specimens. The inclusion in the control group of specimens from two very young infants (1 day and 12 days, respectively) raises the possibility that immaturity was partly responsible for the low mean value of the controls. However, this seems unlikely, as the mucous gland index in the oldest control was about the same as in the youngest. The causes of death in the controls did not become available until after the measurements were complete. Two cases of congenital cystic fibrosis were included in the controls, but there is no indication that this biased the result of the assay. Three of the controls had undergone orotracheal intubation before death: one for a period of four days (76.51), one for two days (65.14), and one for a short period one week before death (77.56). Although mechanical irritation might have induced excessive mucus production, there was no indication that this occurred (Table).

The measurements indicate that the proportion of mucous glandular tissue or mucus in the vestibular folds of SIDS victims was half again as large as in the control group. An increase in the mucous content of acini may be present in Fig 2, left, and comparison suggests that the difference between the SIDS and the control specimens in general may reside in the burden of mucus borne by the glands rather than in the number of glands. The functional importance of the excess is not clear, but it seems reasonable to suppose that it may represent a correspondingly excessive secretion of mucus in the SIDS victims.

The possible bearing of such excess on previously suggested mechanisms of SIDS demands consideration. It is probably pertinent that many experienced anesthesiologists believe excess of mucus in the larynx predisposes to the development of laryngeal spasm if the subject is in a light plane of anesthesia.

One type of apnea, laryngeal spasm, has of course long been postulated as a contributing factor of SIDS,[11-13] and depression of the CNS in sleep with or without periodic apnea as described by Steinschneider[5] and by Guilleminault et al[6,14] might well predispose to a prolonged reflex laryngeal closure response similar to that encountered in the lightest plane of general anesthesia. Angell-James and Daly[15] described reflex apnea and bradycardia in anesthetized dogs secondary to stimulation of receptors in the nose and larynx. They considered this to be a potential mechanism in SIDS. The present results provide a further link in this speculative chain by providing a potential source of abnormal reflex stimulation, namely, excess mucus secreted by the glands of the larynx.

As is well known, there is reason to suspect that minor respiratory inflammatory events predispose the infant to SIDS[1] and such infections might well implicate the mucous glands and intensify their rate of secretions; gross signs of inflammation were not present in our specimens. Thus, the likelihood remains that SIDS may be the common outcome of several different mechanisms.[15,16]

Another factor predisposing to the syndrome may be the shape of the infant larynx. The hoodlike or semiconical shape of the infant epiglottis may be related to the relatively close proximity of the infant larynx to the hyoid bone. This shape occurs transiently in the adult during swallowing, and in the infant perhaps reflects a protective condition of partial closure adaptive to the high frequency of swallowing during sucking.[17] With maturation, the epiglottis gradually becomes straighter, the larynx descends, and the entrance opens more. This maturational aspect of laryngeal biomechanics may contribute to the characteristic age incidence of SIDS, which drops sharply by the sixth month.

This investigation was supported by National Institutes of Health grant HL19975.

Breast-feeding and *Salmonella* Infection

Gene L. France, MD; Daniel J. Marmer, MS; Russell W. Steele, MD

• **Various assays were used to examine chemotaxis, opsonization, phagocytosis, and killing of *Salmonella* organisms by colostral and breast-milk components. Vigorous responses of colostral and milk cells against this organism and nonspecific opsonizing capacity of the aqueous phase of colostrum and milk were demonstrated. An assay with acridine orange was used to directly visualize the phagocytic and killing processes; colostral and milk cells were demonstrated to be more active against *Salmonella* than blood neutrophils. In a restrospective survey, a diagnosis of *Salmonella* infection was confirmed in 253 infants less then 1 year of age. Only 12 infants had ever been breast-fed, and only one near the time he had the disease. During the same period of time, 27% of matched control infants were breast-fed.**

(*Am J Dis Child* 134:147-152, 1980)

There is increasing epidemiologic data supporting the contention that breast-feeding protects infants from gastrointestinal (GI) infection.[1-5] More recently, immunologic in vitro data have demonstrated various host defense mechanisms intrinsic to colostral or breast-milk components, and clinical correlates for these in vitro observations are apparent.[6-8] Human milk may therefore provide basic and often essential aspects of immunity for the neonate whose host defense mechanisms are deficient as determined by many measurements.[9]

The relationship of feeding methods to colonization with some specific GI pathogens has also been investigated. Recovery of attentuated polio viruses,[10] enteropathogenic *Escherichia coli*,[11-13] and *Shigella*[14] were all decreased in breast-fed as compared with bottle-fed infants. The clinical importance of the former two infectious agents has of course decreased notably during the past ten to 20 years. On the other hand, the reported incidence of *Salmonella* GI infection for infants in the United States has actually increased during the past decade.[15] No explanation for this increase is readily apparent. However, during the same period of time, a decline in the practice of breast-feeding has occurred.[3] To test the hypothesis that these developments are related, the present study was designed to examine feeding histories of young infants with *Salmonella* infection and to further evaluate immunologic mechanisms in host colostrum and milk specific for salmonellae.

MATERIALS AND METHODS

Population Studied

Isolations of salmonellae from infants less than 1 year of age in Arkansas during the two-year period from Jan 1, 1977 to Dec 31, 1978 were reviewed. Sources for cases included the epidemiology division of the Arkansas State Health Department, Little Rock, the microbiology laboratory of Arkansas Children's Hospital (ACH), Little Rock, and review of medical records from ACH and the University of Arkansas Hospital, Little Rock. These two hospitals represent the largest medical care facilities for children in the state of Arkansas. Mothers of infected infants were contacted by telephone to determine whether the infants had been breast-fed and, if so, for how long.

Data on general breast-feeding practices were obtained from two populations of mothers, subsequently referred to as clinic and private patients. The clinic group were delivered of their infants at the University of Arkansas Hospital and subsequently received routine care for their children at ACH; this is preponderantly a welfare population. Information regarding private patients was obtained from seven private practices in rural and urban areas throughout the state of Arkansas. In both clinic and private groups, medical charts were reviewed and mothers were questioned either during clinic visits or by telephone to ascertain the length of time they nursed their infants. Approximately 200 cases from the clinic and each private practice were evaluated in this manner.

Collection of Colostral and Milk Samples

Colostrum and milk were obtained from 60 healthy, lactating mothers sequentially at various postpartum periods. Samples were collected by manual expression or with a breast pump and were placed in sterile plastic containers. These were

Reprint requests to Department of Pediatrics, University of Arkansas for Medical Sciences, 4301 W Markham, Little Rock, AR 72201 (Dr Steele).

transported at room temperature and were examined in the assays described below within two hours.

Separation of Peripheral Blood Leukocytes

Heparinized peripheral blood was obtained from normal donors, and neutrophils were separated by 6% dextran sedimentation. Cells were washed twice, quantitated, and resuspended in appropriate medium. Essentially, assays with these peripheral blood neutrophils served as a basis of comparison for data from colostral and milk cells.

Preparation of *Salmonella* Suspension

Salmonella enteritidis, serotype *paratyphi* B originally isolated from a patient with gastroenteritis, was divided into equal portions in trypticase soy broth (TSB) and stored at −70 °C. These aliquots were quantitated by a standard colony count method so that when thawed, reconstituted with a fourfold volume of TSB, and grown at 37 °C for 18 hours, concentrations of bacteria were consistently 1 to 2×10^7 colony forming units per milliliter.

Quantitation of the Cellular Components in Colostrum and Breast Milk

After measuring volume, samples of colostrum and milk were centrifuged at 500 g for 20 minutes at 12 °C. During centrifugation, milk separates into three layers: a cell pellet, a middle layer, and an upper fat layer. The middle layer or aqueous phase was aspirated and stored for studies of opsonization, and the cell pellet was washed three times by centrifugation and was resuspended in Gey's solution. Total cells were quantitated in a hemocytometer. Differential counts were accomplished by preparing a monolayer stained with 0.14% acridine orange and by examining this preparation under fluorescence microscopy. In preliminary studies, differential counts of cytocentrifuged specimens stained with Wright-Giemsa, or nonspecific esterase stains, were more difficult to evaluate. Viability was determined using the trypan blue exclusion method.

Assays of Neutrophilic and Macrophagocytic Function

The following functional properties of colostral and milk neutrophils and macrophages were assayed: chemotaxis, reduction of nitro blue tetrazolium (NBT) dye, and phagocytosis and killing of *Salmonella* bacteria. Chemotaxis of neutrophils and macrophages was measured using the method of migration of cells under agarose gel.[16] In these assays, zymosan was used to activate chemotactic factors from complement. Spontaneous and endotoxin-stimulated NBT dye reduction was performed using the semiquantitative slide method.[17]

Phagocytosis and killing of *Salmonella* bacteria were first measured by the bactericidal method of Quie et al.[18] An assay using acridine orange as a vital stain for bacteria was then used to directly visualize phagocytic and killing processes and to differentiate the effects of neutrophils and macrophages. Live bacteria stain green with acridine orange; the color changes to bright red when the bacteria are killed by phagocytes.

Details of this assay were previously reported.[19] Briefly, monolayers were first prepared by placing five drops of colostrum, milk, or peripheral blood onto flat, glass coverslips and allowing attachment of these cells during an incubation of one hour at 37 °C in 5% CO_2. The supernatant fluid was then removed by gentle washing with normal saline solution, and two drops of *Salmonella* bacterial suspension containing approximately 1×10^8 of bacteria per milliliter in phenol-free Hanks' balanced salt solution with 10% fetal calf serum was placed on the cell monolayers. Coverslips were then incubated on a shaker at 37 °C for 90 minutes. After incubation, monolayers were washed twice with normal saline solution and stained for one minute with 0.14% acridine orange in Gey's solution. Coverslips were mounted face down and examined by fluorescence microscopy. Approximately 100 neutrophils and 100 macrophages were counted, and the total number of bacteria phagocytized was recorded as well as percent killed (red) and alive (green). A phagocytic index was calculated by dividing the total number of intracellular bacteria by the number of phagocytes counted.

Opsonization by Colostrum and Milk

The aqueous phase of colostrum and milk was examined for opsonizing capacity using peripheral blood neutrophils in two assay methods: the bactericidal method of Quie et al[18] and the chemiluminescence assay.[20]

Table 1.—Breast-feeding Practices and *Salmonella* Infection in Infants Less Than 1 Year Old

Population Surveyed	Total Births in Arkansas, Jan 1, 1977-Dec 31, 1978	% Breast-fed	Reported Incidence of *Salmonella* per 1,000 Infants		Significance
			Breast-fed	Bottle-fed	
University clinic	6,000	15	0.00	14.3	$P < .001$
Private	66,000	29	0.05	3.8	$P < .001$
Total	**72,000**	27	0.05	4.8	$P < .001$

RESULTS

Salmonella Infection in Infants

From Jan 1, 1977 to Dec 31, 1978 approximately 72,000 infants were born in the state of Arkansas. During this two-year period, 253 cases of *Salmonella* infection in infants less than 1 year of age were reported, 73 from the university clinic population and 180 from private practices (Table 1). Only one of these infants was being breast-fed at the time of clinical infection. Twelve infants were breast-fed sometime during the first year of life, but such feedings were discontinued an average of four months prior to documentation of *Salmonella* gastroenteritis or sepsis. The shortest interval was one week from discontinuation of breast-feeding to the onset of infection; this represents the single infant whom we considered being breast-fed at the time of infection. Table 1 therefore demonstrates that the incidence of *Salmonella* disease was significantly higher in bottle-fed than breast-fed infants. This difference was greater for clinic patients. The incidence in bottle-fed clinic patients was 14.3 cases per 1,000 infant population as compared with 3.8 per 1,000 in the private population.

Most cases of *Salmonella* infection occurred during the first few months of infancy; 75% of reported cases in this series were actually less than 6 months of age (Fig 1). These included three cases of *Salmonella* meningitis aged 5, 7, and 8 weeks. None of these three patients had sickle cell disease or other predisposing factors.

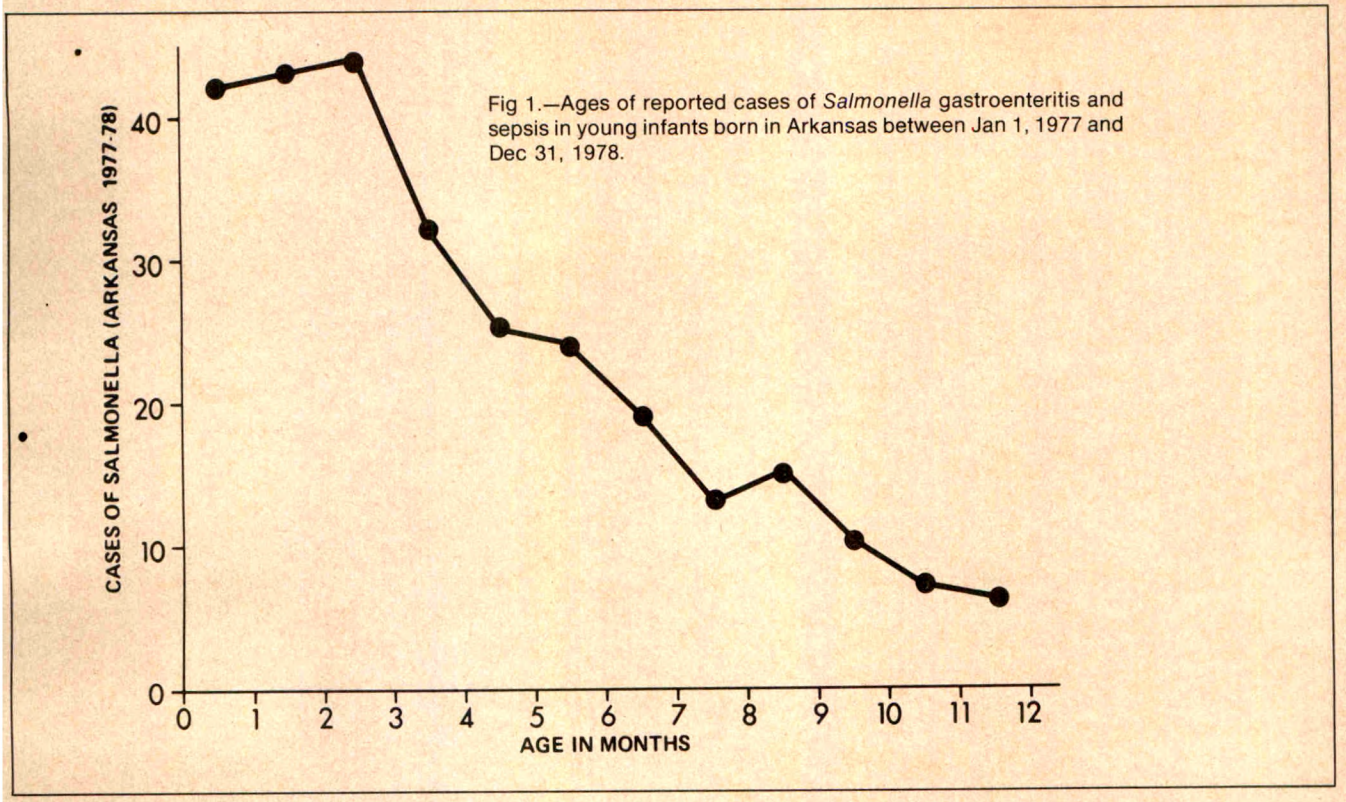

Fig 1.—Ages of reported cases of *Salmonella* gastroenteritis and sepsis in young infants born in Arkansas between Jan 1, 1977 and Dec 31, 1978.

Breast-feeding Practices

Fifteen percent of the clinic population breast-fed their infants as compared with 29% followed up in private practices. Both groups who breast-fed continued for an average duration of four months and this average varied little among seven private practices surveyed. Almost all mothers who elected to breast-feed their infants had discontinued the practice after six months. The percentage of infants breast-fed at various ages for our total population is summarized in Fig 2.

Immunologic Considerations

Total cell counts in colostrum and milk with absolute neutrophil, macrophage, and lymphocyte counts were determined sequentially for 60 healthy lactating women, and results are presented in Fig 3. Neutrophil and macrophage counts are greater than 1×10^7/mL in initial colostral samples, decreasing to 1×10^6/mL by the fourth postpartum day. Subsequently, cell counts remain less than 1×10^5/mL for the duration of lactation. Neutrophils are slightly more prevalent than macrophages until the fourth postpartum day, after which time macrophages constitute approximately 55% of the total cell content. Breast engorgement did not seem to influence total or neutrophil cell counts. Colostral and breast-milk samples from nonnursing mothers, one to four days postpartum, obtained during pumping for painful engorgement, showed counts similar to those from breast-feeding mothers.

Colostral and breast-milk cells did not respond to chemotactic factors generated from complement in fresh whole serum. Moreover, neither the aqueous phase of colostrum nor the aqueous phase of milk seem to contain enough complement or other chemotactic factors to influence the migration of peripheral blood neutrophils.

Resting metabolic activity in colostral neutrophils and macrophages was greater than for peripheral neutrophils as measured by the NBT Assay. An average of 24% (range, 11% to 34%) of colostral neutrophils and 19% (7% to 36%) of macrophages were NBT-positive as compared with 9% (2% to 17%) of blood neutrophils. Endotoxin increased the percent of NBT-positive colostral neutrophils to 56% (51% to 62%) but did not increase the percentage of NBT-positive macrophages; peripheral blood neutrophils in stimulated preparations average 72% (55% to 90%) positive cells.

Both bactericidal assays demonstrated vigorous phagocytic and killing capacity of colostral and milk cells against *Salmonella* organisms (Tables 2 and 3). Activity was comparable to peripheral neutrophils with the colony count method (Table 2), but the acridine orange assay, a bacteria-saturated system (Table 3), indicated that breast cells phagocytize more bacteria than peripheral neutrophils. Macrophages seem more active than breast neutrophils for both phagocytizing and killing of *Salmonella* organisms.

Opsonization of *Salmonella* bacteria by the aqueous phase of colostrum and milk as measured in the chemiluminescence assay appears in Fig 4. The initial rate of chemiluminescence is not as rapid as with whole fresh serum but is comparable to results with inactivated serum. Heating of colostrum or milk to 56 °C for 30 minutes does not alter this opsonizing capacity.

COMMENT

The present study was designed to comprehensively examine all aspects

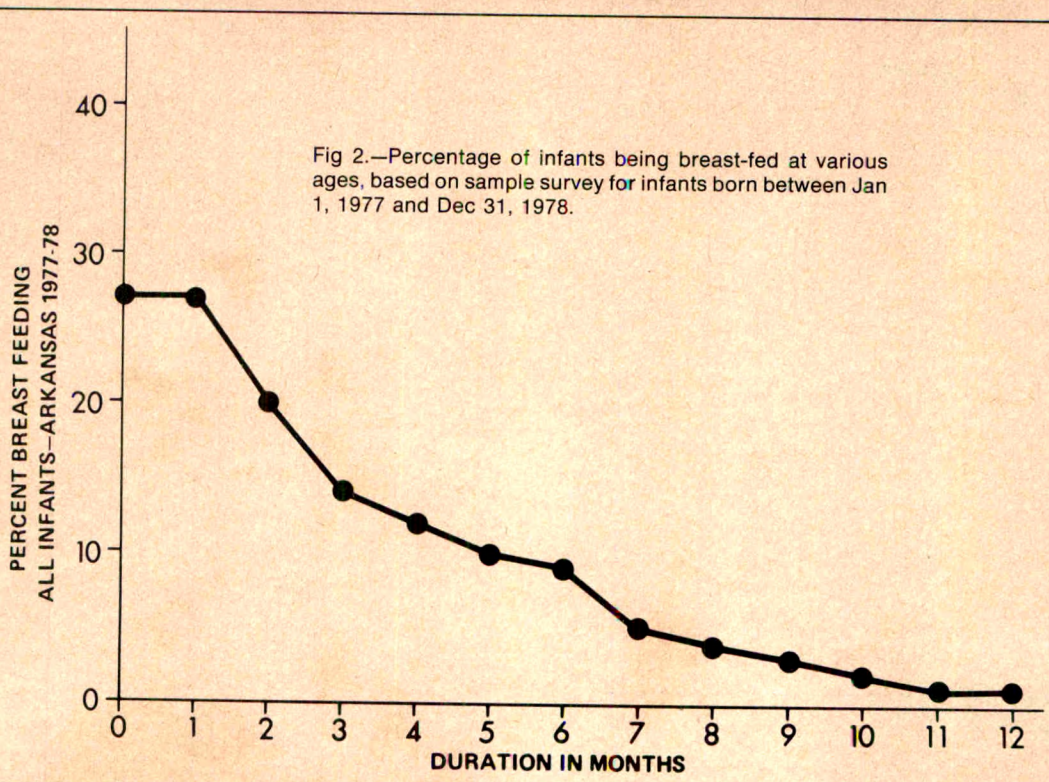

Fig 2.—Percentage of infants being breast-fed at various ages, based on sample survey for infants born between Jan 1, 1977 and Dec 31, 1978.

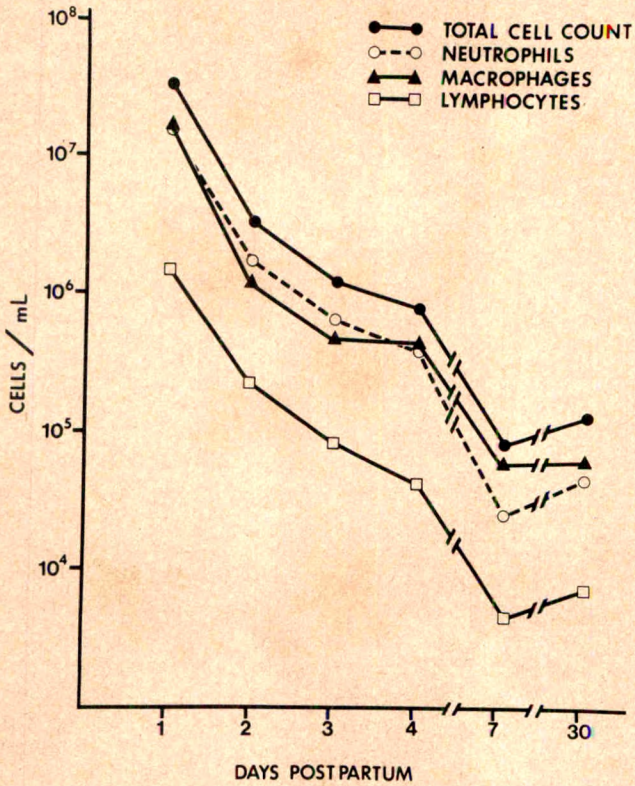

Fig 3.—Geometric mean concentration of total cells, neutrophils, macrophages, and lymphocytes in colostral and milk samples collected sequentially from 60 lactating donors.

of phagocytic function from their migration into colostrum and breast milk to final killing of a specific pathogen. By most in vitro variables evaluated, these phagocytic cells were active against *Salmonella* organisms and therefore seem to provide important mechanisms of host defense for the breast-fed infant. Such data was anticipated since *Salmonella*, an intracellular bacterium, is particularly susceptible to macrophagocytic killing processes.

Results determining the cellular content in colostrum and milk are similar to those reported previously[6,8,21] although some investigators have not observed high concentrations of neutrophils.[22,23] In the latter reports, either Wright-Giemsa or nonspecific esterase stains of cytocentrifuged specimens were examined. Often, these methods result in fragmenting of the neutrophils; moreover, differential counts based on cellular morphology are difficult with these stains. We found more consistent and more interpretable results using an acridine orange stain of living cells in a monolayer.

Unlike peripheral neutrophils and monocytes, colostral and breast-milk

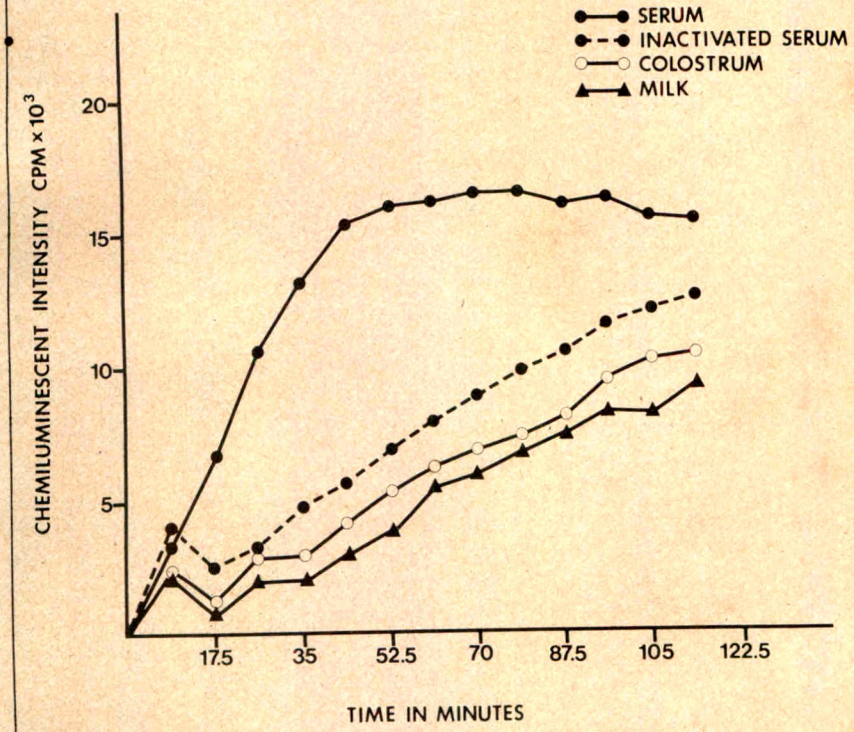

Fig 4.—Temporal traces of chemiluminescence from 5 × 10^6 polymorphonuclear leukocytes after the addition of *Salmonella enteritidis*, serotype *paratyphi* B, which was first opsonized with various fluids. Bacteria added to buffer alone and then combined with leukocytes yielded no chemiluminescent response at any time interval studied. CPM indicates counts per minute of photoemission.

cells do not respond to chemotactic factors in vitro. Breast milk itself contains only low concentrations of complement components such as C3 and C4,[13] probably too low to generate adequate chemotactic factors in vivo to influence migration of neutrophils or macrophages. If the complement was present in substantial quantities, its heat and acid liabilities would render it nonfunctional once reaching the infant's GI tract. Components other than complement in breast milk, which might provide chemotactic activity, have not been described.

The elevated resting values for the NBT dye reduction assay indicate that phagocytes in colostrum and breast milk are more metabolically active than those in peripheral blood. This may be the result of the active phagocytosis of fat particles by breast-milk cells. Also, essentially all colostral and milk samples are colonized by bacteria regardless of the care in collection, and such contamination may elevate phagocytic and thus metabolic activity.

Neither aqueous phase colostrum nor milk opsonize *Salmonella* for phagocytosis by peripheral neutrophils using the standard colony count assay. However, opsonization was appreciated in the chemiluminescence assay. Methodology alone may account for the discrepant results. In the colony count assay, a bacteria-to-cell ratio of 1:1 is used whereas in the chemiluminescence assay, the preparation is saturated with bacteria, yielding a ratio of approximately 100 bacteria per phagocyte. The latter assay allows optimal contact for phagocytes and bacteria. Modifications of the colony count assay have been used with other bacteria, and opsonization by aqueous phase milk or colostrum has been demonstrated.[7] Other studies using this assay have demonstrated that colostrum and milk actually protect bacteria from the effects of phagocytic cells.[6]

The clinical data in this study also strongly support a major role for breast-feeding in protection against *Salmonella*. Breast-fed infants have a significantly ($P < .001$) lower incidence of infection. The only alternative possibility is that other aspects of care for breast-fed infants are in some way different so that contact with *Salmonella* bacteria is decreased. To examine this hypothesis, the source of *Salmonella* exposure in infants must be determined. Unfortunately, this information is not generally reported to the Center for Disease Control, Atlanta, or other surveillance programs. The common modes of transmission including contaminated food, water, household pets, and person-to-person contact have rarely caused recognized outbreaks in infants. Environmental cultures were obtained in many of the present cases. Samples of

the water supply were all negative, and only occasionally was *Salmonella* cultured from the mother or other family members. Certainly, a prospective study designed to examine various aspects of infant feeding and care might delineate a source of infection, and such a study is currently in progress at our institution.

The highest incidence of *Salmonella* infection occurred during the first few months of life (Fig 1). This is an important observation since most mothers prefer to nurse their infants for just a few months (Fig 2). Therefore, considering the present protection data, recommendations need not emphasize breast-feeding for long periods of time. Furthermore, because the feedings of many breast-fed infants in the present study were supplemented with bottle feedings, the resulting partial breast-feeding seems to offer equally effective protection from *Salmonella* infection. On the other hand, such protection from *Salmonella* lasts only while breast-feeding is continued; 12 infants who were nursed for some period of time subsequently became infected after breast-feeding was discontinued.

Breast-feeding is not the only factor influencing propensity to *Salmonella* infection. If it were, a higher incidence would be expected after women cease nursing their infants. Since this was not noted, other factors must play a role. Such factors would include increased susceptibility of the extremely young infant secondary to either inadequate host responses or to increased exposure from an environmental source.

Previous studies have demonstrated that the protective properties of breast milk are more evident among the lower socioeconomic segment of the population. Similarly, our data show greater protection of breast-feeding for a defined welfare population as compared with a preponderantly middle class group. Some differences in our incidence of *Salmonella* for clinic vs private patients must be attributed to methods of reporting. This study was primarily conducted by investigators serving the university clinic population, and it is expected that reporting and follow-up of these patients was better. It is doubtful, however, that the almost fourfold greater incidence in the university clinic population could be accounted for by reporting practices alone. We therefore conclude that breast-feeding should be encouraged particularly for the lower socioeconomic segment of our population. Unfortunately, the trend has been just the reverse. Actually, fewer mothers in this socioeconomic group breast-feed as demonstrated in the present study (Table 1).

Three cases of *Salmonella* meningitis were recognized during the study period, and all cases were in infants less than 3 months of age. Thus, one out of every 40 cases of *Salmonella* infection in the 0- to 3-month age group resulted in systemic dissemination. Aggressive treatment and follow-up of the extremely young infant with *Salmonella* infection is certainly warranted.

A decline in the practice of breast-feeding during the previous two decades may have contributed to an increased incidence of *Salmonella* infection in infants. This association may also apply to other GI and respiratory pathogens. Pediatricians should therefore strongly consider host resistance factors provided by breast milk in formulating their approach to antepartum counseling. There is additional reason to particularly encourage routine breast-feeding for the lower socioeconomic populations in this country.

This project was started by the Department of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, to acknowledge active participation in the International Year of the Child, 1979. Janet Schneider provided editorial assistance. Paul C. White, Jr, MD, epidemiologist and Director of Communicable Disease Control for the state of Arkansas, provided *Salmonella* epidemiologic data.

Fibromuscular Hamartoma of the Esophagus in an Infant

Robert C. Beckerman, MD; Lynn M. Taussig, MD; Richard C. Froede, MD; Stanley W. Coulthard, MD; Hugh Firor, MD; Ina Tonkin, MD

An 11-month-old infant had a history of dysphagia and continuous drooling without evidence for airway obstruction. A biopsy specimen of a neck mass on the left side adherent to the larynx and esophagus demonstrated pathologic features characteristic of a fibromuscular hamartoma. Upper airway obstruction subsequently ensued and the patient was managed for 16 months with a tracheostomy and feeding gastrostomy. Although posing an extremely difficult management problem, this benign tumor was surgically removed without damage to the larynx when the patient was 28 months old. The differential diagnosis of this unusual lesion must consider congenital fibromatosis and fetal rhabdomyoma.

(*Am J Dis Child* 134:153-155, 1980)

A hamartoma may be defined as an excessive focal growth of mature normal cells and tissues in an organ or tissue composed of identical cellular elements.[1] This type of benign developmental tumor rarely has been observed in infancy and childhood and in only four instances have such tumors been reported in the region of the trachea and esophagus in any age group.[2-5] We have recently diagnosed and surgically treated a fibromuscular hamartoma that compressed and obstructed both the cervical trachea and esophagus in an infant whose major initial symptom was dysphagia. This histologically benign tumor presented an extremely difficult management problem because of its location.

REPORT OF A CASE

This 2-year-old boy was first hospitalized at 11 months of age because of failure to gain weight since 6 months of age. He was the product of a full-term uncomplicated pregnancy and was born weighing 3.2 kg after a normal labor and vaginal delivery. The neonatal course was unremarkable. He was breast fed and had no reported feeding difficulties during the first several months of life. He tolerated strained baby foods, but when "table foods" were added at two months of age he began to spit out most of what was fed to him. He continued to gain weight until approximately 6 months of age but then lost about a kilogram during the next five months. There was no history of excessive emesis or diarrhea. All solid foods were either refused or caused gagging. Drooling was incessant. He had two episodes of bronchitis during this first year of life. There was no history of stridor, pneumonia, or cyanosis with feeding. Physical examination showed a thin child whose weight was 6.38 kg (third percentile for age); height, 71 cm (tenth percentile for age); and head circumference, 44.5 cm (tenth percentile for age). The child constantly drooled copious amounts of saliva. There was a generalized decrease in subcutaneous fatty tissue. The auricular and oral cavities were unremarkable. There were shotty but firm posterior cervical and inguinal lymph nodes. The trachea was deviated to the right by a soft-tissue mass situated at the junction of the cricoid cartilage and trachea on the left side of the neck. The cry was qualitatively normal, but mild inspiratory stridor was heard over the trachea. Results of cardiopulmonary and abdominal examinations were normal. There were no neuromuscular deficits. Laboratory evaluation showed the following values: WBCs, 15,000/cu mm; hemoglobin, 12.4 g/dL; hematocrit, 37%; total serum proteins, 7.6 g/dL; albumin, 4.4 g/dL; BUN, 7 mg/dL; serum creatinine, 0.5 mg/dL; and glucose, 85 mg/dL. The chest roentgenogram (Fig 1) showed noticeable deviation of the trachea to the right at the level of C3-4. A cine-esophagogram showed pharyngeal incoordination with reflux of barium into the nasopharynx and a large posterior indentation of the esophagus at the region of the cricopharyngeus muscle (C3-4). A xeroradiograph of the neck showed deviation of the trachea anteriorly and to the right by a mass at the level of C3-4 (Fig 2). Bronchoesophagoscopy showed that the trachea was partially compressed and the esophagus was almost completely obstructed by the mass lesion.

The neck was explored via a collar-type incision and a firm mass was visualized at the junction of the trachea and larynx that displaced the trachea to the right and encompassed the esophagus posteriorly. Biopsy of the mass yielded fragments of whitish-tan hemorrhagic tissue. The pathologic report raised some questions as to whether the mass had actually undergone a biopsy. Therefore, a few days after the initial biopsy, the neck incision was reopened and another biopsy specimen obtained from deeper within the mass lesion.

Because of progressive airway obstruction after the biopsy, a tracheostomy and feeding gastrostomy were performed. The clinical course over the next 16 months was complicated by recurrent aspiration pneumonia that resulted in mild chronic interstitial lung disease. The tumor was completely resected when the patient was 28 months of age. Postoperative convalescence was unremarkable. The patient was discharged from the hospital and followed up closely for tracheostomy and gastrostomy care. Within four weeks of removal of the tumor, his swallowing function had improved dramatically and he was able to swallow liquids and foods; his gastrostomy tube was then removed. His tracheostomy tube has not yet been successfully removed because of a mucosal flap causing obstruction proximal to the tracheostomy stoma. However, placement of a small tracheostomy tube has allowed him to develop normal speech for his age.

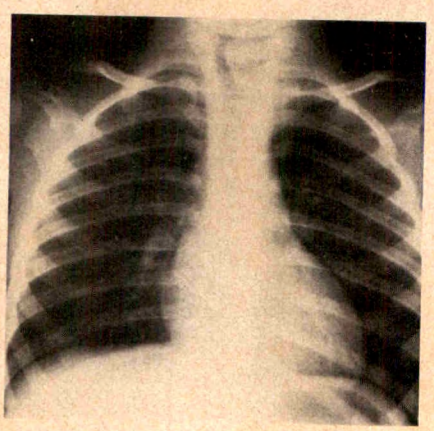

Fig 1.—Posteroanterior chest roentgenogram. Trachea is noticeably deviated to right at level of C3-4. Lung fields are clear.

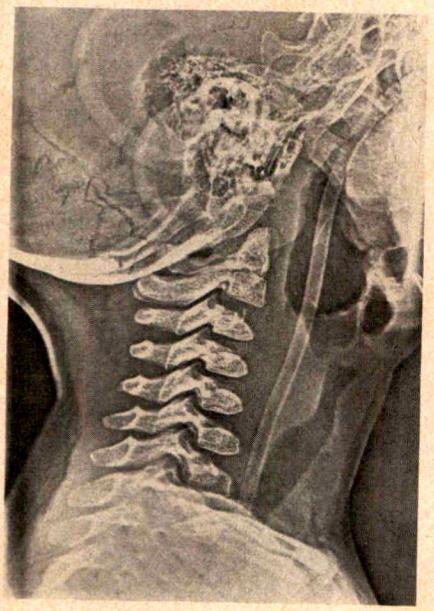

Fig 2.—Xeroradiographic examination demonstrates anterior bowing of tracheal air column at level of C3-5.

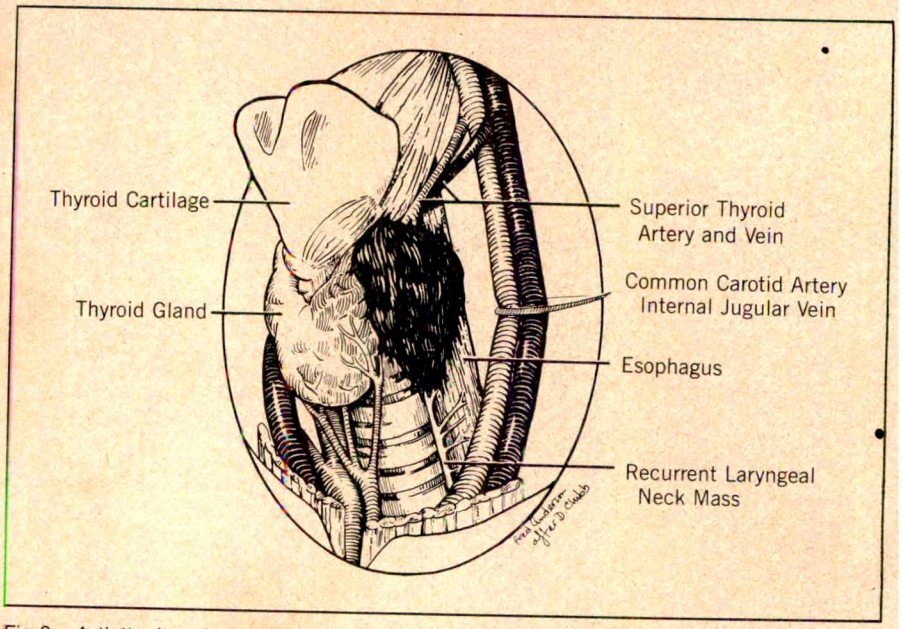

Fig 3.—Artist's description of tumor mass with respect to surrounding structures. Drawn from photographs obtained at surgery when mass was removed.

SURGICAL APPROACH

So as to minimize morbidity, an attempt at definitive extirpation of this tumor was delayed until the infant had grown more. The apparent attachment of the tumor mass to both the trachea and esophagus in the tracheoesophageal groove suggested that part or all of the larynx may have to be removed with the mass. At 28 months of age, after the child had grown, it was decided to remove the mass because of the recurrent pneumonias and persistent tracheoesophageal obstruction.

The tumor was again approached through an incision in the left side of the neck (Fig 3). The carotid sheath was retracted laterally, and the thyroid gland and the tumor attachments to the trachea and esophagus were identified. The tumor mass was gently delineated and dissected free from the larynx and trachea, leaving these structures intact. The major mass of tumor seemed to originate from the left lateral wall of the cervical esophagus. A portion of the esophagus and the superior lobe of the left thyroid were removed with the mass. The defect in the esophagus was closed. Examination of the remaining esophagus showed no evidence of residual tumor.

PATHOLOGIC FINDINGS

The initial biopsy specimen of the mass showed, on frozen and permanent sections, striated skeletal muscle with atrophic changes. The atrophic muscle bundles were surrounded by small oval to spindle-shaped mesenchymal cells resembling fibrous connective tissue of varying degrees of differentiation. The second biopsy specimen consisted of three small segments of whitish tan tissue with focal areas of hemorrhage. Histologically, the tissue had three mesenchymal elements: skeletal muscle fibers, fibrous connective tissue, and hyaline cartilage (Fig 4). The skeletal muscle consisted of mature muscle fibers arranged in a fascicular growth pattern. The fibrous connective tissue exhibited various degrees of maturity, and the hyaline cartilage and perichondrium were fairly immature in growth pattern. These findings presented the following two distinct diagnostic possibilities: either an exuberant young fibromatosis or a hamartomatous malformation. There was no evidence of malignant transformation in multiple sections.

The entire tumor mass was removed in two pieces of firm whitish yellow tissue, the largest measuring 2.5 × 1.5 × 1.5 cm. Multiple sections of this mass showed striated muscle fibers with varying degrees of differentiation. Cross striations were evident. The muscle fibers retained their fascicular pattern with interlacing of fibrous connective tissue. A segment of thyroid tissue adjacent to the muscle mass showed the main mass to be compressing it, with atrophy of adjacent follicles. There were several focal areas of muscle and connective tissue projections into the thyroid stroma. Cartilage was also observed and the surrounding tissue showed chronic inflammation and focal hemorrhage. A section through the esophageal mucosa and submucosal area showed

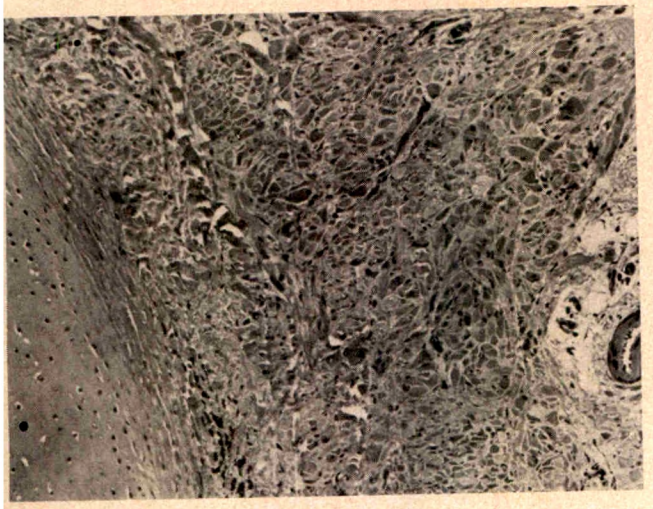

Fig 4.—Intermixture of skeletal muscle, fibrous connective tissue, and hyaline cartilage (hematoxylin-eosin, ×63).

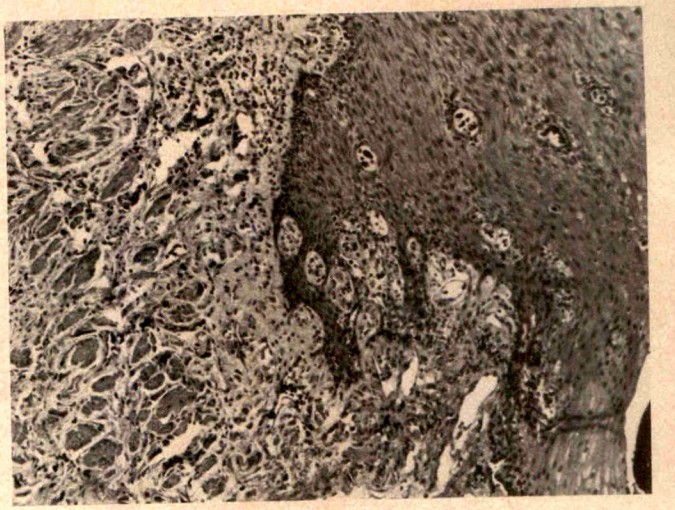

Fig 5.—Esophageal mucosa with fibromuscular tissue directly beneath (hematoxylin-eosin, ×63).

the tumor mass to lie directly beneath the mucosa (Fig 5).

COMMENT

Based on the presence of skeletal muscle, cartilage, and the peculiar and unexplained perineural-muscle changes, the lesion was classified as a hamartoma. Because of the infiltrative pattern noted, a form of congenital fibromatosis was also considered. However, the maturity of the muscle, the presence of the connective tissue in the periphery of the mass, and the presence of the cartilage were more suggestive of a hamartomatous lesion than a fibromatous malformation. A fetal rhabdomyoma was also considered, but because of the highly organized configuration of the skeletal muscle, this diagnosis was excluded. The pathologic slides were reviewed by the Armed Forces Institute of Pathology, Washington, DC, which concurred with the diagnosis of hamartoma by Franz M. Enzinger, MD (written communication, June 1978).

Hamartomas are uncommon benign developmental tumors that may occur in all organs of the body. Similar types of tissue normally exist in the region in which the hamartoma is found, but the tumor tissue has escaped organization and may be poorly differentiated and found in excess of what is to be expected. In hamartomas, the cellular components are usually mature showing no anaplasia but occasionally evidence of structural disorganization. It is for this reason that they are classified as congenital malformations. Many hamartomas do not have the ability for continuous growth and, therefore, can only be considered to be tumor-like malformations. There are others that do show progressive proliferation, a basic characteristic of a true tumor.

A review of the literature[2-5] shows scant information concerning congenital hamartomas in the cervical region. Stout and Lattes[5] discussed benign mesenchymomas, using hamartoma as one of the synonyms. They listed a number of lesions as mesenchymomas, including mixed mesenchymal tumors, angiomyolipomas lipomyomas, angiolipomas, and mesenchymal hamartomas.

Benign developmental tumors accounted for 71% (190/267) of a large series[6] of neck masses in infants and children and, thus, such tumors are relatively common. That study, however, did not report the occurrence of a single hamartoma. To our knowledge, hamartomas involving the cervical structures have only been reported previously in four patients, two of whom were children.[2-5] Three of the cases reported were polypoid intraluminal esophageal hamartomas, histologically composed of either gastric mucosa[2] and cartilage[2,3] or respiratory epithelium and fibrotic connective tissue.[4] The fourth case, a 3-month-old infant, had a tumor that histologically showed an admixture of myxoidchondromatous, lipomatous, and vascular components but no specific skeletal muscle tissue. Our patient's hamartoma, however, was composed of poorly differentiated striated muscle cells, cartilage, and fibrous tissue and appeared to originate from the external esophageal wall. It is interesting to note that after incomplete excision, recurrent tumors may consist of only one of the elements of the original tumor.

Hamartomas need to be considered in the differential diagnosis of neck masses in children. They may pose difficult management problems that often require emergency care. However, these tumors can be successfully removed without damage to the larynx.

Naloxone

Underdosage After Narcotic Poisoning

Roger A. Moore, MD; Barry H. Rumack, MD;
Christopher S. Conner, Pharm D; Robert G. Peterson, MD, PhD

• A case of propoxyphene hydrochloride (Darvon) poisoning was unresponsive to therapeutic doses of naloxone hydrochloride in a 2½-year-old girl. Following prolonged coma and artificial ventilation for three hours, the patient responded immediately to the intravenous administration of 2 mg of naloxone hydrochloride, which is 20 times the manufacturer's recommended dosage. Naloxone is the agent of choice in reversing the effects of narcotics and synthetic opiate derivatives, such as propoxyphene and pentazocine. The manufacturer's present recommended dosage may not be sufficient to reverse the effects of large narcotic ingestions. We therefore recommend that if there is no response within two minutes of the initial 0.01 mg/kg dosage of naloxone hydrochloride, a second dose 0.1 mg/kg (ten times the manufacturer's suggested dose) be given.

***(Am J Dis Child* 134:156-158, 1980)**

Naloxone hydrochloride is recommended for the reversal of narcotic-induced symptoms.[1] Numerous reports document naloxone's effectiveness in antagonizing the actions of a variety of narcotic drugs, including diphenoxylate hydrochloride,[2,3] propoxyphene hydrochloride,[4,5] pentazocine,[6] morphine,[7,8] and dextromethorphan.[9] Unlike levallorphan tartrate and nalorphine hydrochloride, which can produce severe agitation[8] as well as respiratory depression with reduced tidal volume and rate,[10] the only side effect associated with high-dose naloxone therapy in normal subjects has been a mild feeling of sleepiness.[11,12]

Since 31% of children in comas due to barbiturate ingestion are seen initially with miosis (88% in narcotic ingestion),[13] the advantage of using naloxone as opposed to other narcotic antagonists in a therapeutic trial is clear. No further respiratory compromise will be induced in patients with nonnarcotic poisonings. At present the manufacturer's recommended dose in children with suspected narcotic toxicity is 0.01 mg/kg of naloxone hydrochloride given intravenously (IV), intramuscularly, or subcutaneously[14] and repeated every two minutes as needed to a maximum of three dosages. As the following case history illustrates, a larger initial dose may be necessary.

REPORT OF A CASE

A 2½-year-old girl was in good health until noon on the day of admission, when she had a tonic-clonic seizure. During transport to Denver General Hospital, the child had two additional seizures and due to increasing respiratory distress, she was immediately intubated on arrival. An arterial blood sample revealed a pH of 7.21, a PO_2 110 mm Hg, and a PCO_2 of 42 mm Hg. A fourth seizure was controlled with 2 mg diazepam IV, and 10 g of glucose was given IV without clinical effects. Physical examination revealed a comatose child with miotic pupils; pulse rate was 110 beats per minute, respirations were 24/min, temperature was 37.2 °C, and blood pressure was 80/P. Although the mother strongly denied the possibility of drug ingestion, 0.1 mg of naloxone hydrochloride (0.01 mg/kg) was given IV without clinical response. Due to persistent ventricular tachyarrhythmias, the child then received 10 mg of lidocaine hydrochloride IV, with improvement of the arrhythmia. One and one-half hours after arrival in the emergency room, the child was transferred to pediatric intensive care where her stomach was lavaged with 2 L of normal saline followed by instillation of 15 g of activated charcoal and 2.5 g of magnesium sulfate.

Initial laboratory studies yielded a hematocrit value of 33% and a WBC count

of 20,000/cu mm, with 36% polymorphonuclear leukocytes, 1% basophils, and 55% lymphocytes. Results of automated chemical analysis with six- and 12-channel systems were within normal limits, except for a SGOT value of 65 units, a lactic dehydrogenase value of 280 units, and a serum alkaline phosphatase level of 265 units. The CSF was normal, and arterial blood gases were stable. The Rocky Mountain Poison Center suggested that 2 mg (20 times the recommended dose) of naloxone hydrochloride be administered IV. Clinical improvement was seen within seconds, and the child was active and alert within two minutes. She was extubated 30 minutes later and her condition remained stable throughout the night; she required only one further dose of 1 mg of naloxone hydrochloride.

That evening the toxicology laboratory reported that the gastric aspirate was strongly positive for propoxyphene and that the serum level was 0.45 mg/dL. Therapeutic levels of propoxyphene are less than 0.2 mg/dL and toxic symptoms occur at higher levels. The mother also reported that she found an open bottle of 65-mg tablets of propoxyphene hydrochloride (Darvon) under her dresser at home.

COMMENT

A comatose child brought to a busy emergency room can present a very perplexing problem. The history is frequently unreliable or misleading. The presence of constricted pupils should immediately alert the physician to the possibility of narcotic ingestion, but other drugs including phenothiazines, ethanol, and barbiturates as well as CNS injuries and infections can cause pupillary constriction.[13] The patient in our report did receive a single therapeutic trial of naloxone at the manufacturer's recommended dose. Owing to lack of clinical response, the physician decided to look elsewhere for an etiology of the child's seizures and coma. Had a larger initial dose of naloxone been given, the child may not have had to suffer three additional hours of coma and artificial ventilation.

The site of narcotic agonist and antagonist action is specific opiate receptors on the synaptic membranes of the amygdala, hypothalamus, and thalamus.[15,16] By combining with these receptors, the narcotic blocks the motivational-affective components of pain without affecting the sensory conponent. Naloxone and other narcotic antagonists are believed to act by competing for these receptor sites.[11,17,18] Therefore, the greater the amount of narcotic ingested the larger the amount of antagonist needed to competitively inhibit its effect. Antagonists have been found to reverse ten to 100 times the dose of narcotic. This is primarily due to enhancement of antagonist binding in the presence of sodium.[15,19] Since the receptors lie in the sodium-rich interstitial fluid, there is increased affinity for the antagonists compared with the agonists. In spite of this increased affinity, the point remains that the more narcotic taken the larger the amount of antagonist needed to reverse its effect.

High doses of naloxone in the normal subject produce only mild subjective side effects.[11,12] Nausea and vomiting frequently occur after an injection of naloxone in patients who have been under anesthesia[7] and occasionally with narcotic overdoses, but this response is not dose related. There have been recent reports of ventricular irritability[20] and hypertension[21] after the use of naloxone in patients who have undergone cardiac surgery, but again this is not considered to be dose related and a definite cause-effect relationship has not been established. Early studies of naloxone in man used as much as 20 mg IV[22] and 75 mg subcutaneously[23] as single doses without any adverse reactions. Rumack and Temple[2] reported the case of a 2½-year-old child who had ingested a mixture containing diphenoxylate hydrochloride (Lomotil) and inadvertently received 20 mg of naloxone hydrochloride IV (approximately 2 mg/kg or 200 times the recommended dose); the child's clinical response was good and no adverse effects occurred. Administration of doses up to 5.6 mg/kg in dogs has not resulted in adverse effects on the cardiovascular system.[24] The question remains why suggested initial recommended doses of naloxone are so small while the need for larger doses to obtain adequate clinical response has been previously recognized.[18] We suggest that the manufacturers revise their recommendations to indicate the administration of larger doses to patients who are unresponsive.

Our recommendation for the initial management of a comatose child with possible narcotic intoxication is to give an immediate trial dose of 0.01 mg/kg of naloxone hydrochloride (the manufacturer's recommended dose) followed in two minutes by 0.1 mg/kg of naloxone hydrochloride (ten times the manufacturer's recommended dose) if no clinical improvement is seen. Due to the lack of toxicity of naloxone, the dose should not be smaller than 0.1 mg/kg. In our experience, this dosage protocol has proven safe and effective in over 1,800 cases of narcotic ingestion in children since 1972, with no adverse sequelae. Therefore, all children who receive the initial 0.01 mg/kg dose and show no response must receive the second larger dose or the therapeutic trial is incomplete. If the child is convulsing, anticonvulsants should be withheld until this trial is completed, since further depression in respiratory status and state of consciousness may be produced by the anticonvulsant. Also, naloxone has been suggested as being therapeutic in the control of certain narcotic-induced seizures.[4] Since the half-life of naloxone is short[25] in comparison with the half-lives of most narcotics, the child needs to be observed closely for return of narcotic symptoms. Repeated doses of naloxone may be necessary until the narcotic is metabolized and excreted. If required, repeated doses of naloxone should be given in the same dose that produced initial reversal of symptoms.

The use of naloxone in older children or young adults with a history of narcotic use or evidence of addiction is a concern of most emergency room physicians. However, in our experience, the use of naloxone in addicts has resulted in a brief withdrawal syndrome without detrimental effects. The use of naloxone should not be withheld in situations where the patient is suspected of being an addict.

Emesis or lavage should always be performed since delayed gastric emptying is common following narcotic ingestions.[2] Emesis can be

induced in the alert patient, but if seizures or coma exist, tracheal intubation and gastric lavage with a large bore (28-French or larger) Ewald tube should be carried out. Activated charcoal, five to ten times the estimated weight of ingested drug (minimum of 10 g), as well as a nonabsorbable saline cathartic (sodium sulfate or magnesium sulfate, 250 mg/kg of body weight) should be instilled following emesis or lavage. Administration of the cathartic should be repeated every three to four hours until stooling has occurred. Of course, other basic supportive measures should be provided for the child as needed.

60 YEARS AGO IN THE AJDC

The Elimination of Acetone Bodies During Infectious Fevers

The elimination of acetone bodies (acetone, diacetic acid and beta-hydroxy butyric acid) has been documented previously during the course of some infectious diseases. Quantitative studies, especially as related to the type and degree of sickness with specific illnesses, have not been studied. The normal child eliminates 20 to 100 mg daily. Forty-one children who had scarlet fever, diphtheria, measles and pneumonia were studied. Of these only twenty-four showed acetone excretion above normal levels; in some of these the amount was only slightly elevated over normal.

There appeared to be no correlation of acetone found with the type of illness, the height or duration of the fever or the extent of prostration of the child. Some who excreted large amounts were not remarkably ill. The decrease in food intake, a consistent part of infectious diseases, did not appear to be an important or consistent relationship.—Borden S. Veeder, MD, Meredith R. Johnston, MD, Capt USA, Washington University School of Medicine, St Louis (19:141, February 1920).

Infectious Mononucleosis Initially Seen as Cold-Induced Acrocyanosis

Association With Auto-Anti-M and Anti-I Antibodies

Joseph D. Dickerman, MD; Philip Howard, MD; Sarah Dopp, MT (ASCP); Richard Staley, MD

• A case of infectious mononucleosis initially seen as cold-induced acrocyanosis is discussed. Serological evaluation of the patient showed the presence of auto-anti-M and anti-I antibodies. Both the M and I antigens are normally found on RBCs. It is postulated that one or both of these antibodies were responsible for the acrocyanosis.

(*Am J Dis Child* 134:159-160, 1980)

Infectious mononucleosis is a disease that can have a variety of signs and symptoms.[1,2] A case of infectious mononucleosis was initially seen as cold-induced acrocyanosis. To the best of our knowledge, this is the first report of such a clinical presentation.

Serological evaluation of the patient showed the presence of cold agglutinating anti-I and auto-anti-M antibodies. The I antigen is normally present on most adult RBCs. The M antigen is present on the RBCs of about 75% of all people. We are unaware of other cases of infectious mononucleosis where the presence of an auto-anti-M antibody has been demonstrated.

REPORT OF A CASE

In August 1975, a 5-year-old boy was admitted to the Medical Center Hospital of Vermont, Burlington, with a three-day history of swollen lymph nodes, left earache, and mild sore throat. He had received oral penicillin G potassium for the last two days. Three days prior to admission, the patient's mother noted that his tongue turned blue after he had eaten vanilla ice cream. On several occasions over the next two to three days, the patient's nose, lips, fingers, and toes were noted to turn blue. These episodes lasted for a few minutes and were usually relieved by warming the child. The blue toes were noted particularly after the child played on linoleum or on a hardwood floor early in the morning, and the toes returned to their normal color once the patient was removed from the floor. There was no previous history of cardiac or pulmonary disease and no previous history of cyanosis or intolerance to cold. Results of physical examination were essentially within normal limits except for the following: he appeared mildly ill; his temperature was 37 °C; the pharynx was inflamed, with severely enlarged tonsils that were coated with large patches of a white, cheesy exudate; there were large, tender anterior cervical lymph nodes and some nontender posterior cervical lymph nodes; and, the spleen was palpated 4.5 cm below the left costal margin. No clubbing, icterus, or cyanosis was noted. Several attempts to obtain blood by a finger-stick technique resulted in instantaneous clotting in the small capillary tubes. A small sample of blood was obtained by venipuncture and placed in a refrigerator. After ten minutes, severe agglutination of the RBCs was noted. This agglutination was reversible by hand-warming the sample.

The hematocrit level was 37%, and the hemoglobin level was 12.0 g/dL. The WBC count was 13,000/cu mm, with 21% segmented neutrophils, 6% band forms, 70% lymphocytes, and 3% monocytes. Many of the lymphocytes were atypical in appearance. The RBCs and platelets appeared clumped on the peripheral blood smear. A throat culture was negative for group A streptococci. A slide test for heterophil antibody of infectious mononucleosis was strongly positive on two occasions. The results of urinalysis were within normal limits, except for a moderate amount of ketones. The platelet count was 300,000/cu mm, the reticulocyte count was 1.2%, and the prothrombin time was 11 s, with a control of 11.8 s. The partial thromboplastin time was 31 s, with a control of 30 s. The venous clotting time was seven minutes (normal, <15 minutes). The fibrinogen level was 268 mg/dL (normal, 190 to 440 mg/dL), and a cold agglutinin titer was positive at 1:1,024 dilution. An ox-cell hemolysin titer was positive at 1:640 dilution.

The patient was typed as blood group A_1 and his RBCs were agglutinated by all of

four different anti-M typing sera. The direct Coombs' reaction was initially positive. During the clinical illness, his serum was found to contain both anti-M and anti-I antibodies, with much stronger reactions occurring at lower temperatures (anti-M titer 1:1,024, anti-I titer 1:512 at 4 °C), although weaker reactions could be observed at body temperature (anti-M titer 1:64 and anti-I titer 1:16 at 37 °C). The patient's own M-positive RBCs were agglutinated by his serum and absorbed anti-M from the serum at low temperatures. The anti-M could be recovered subsequently by elution of the cells.

Serum obtained six months after cessation of clinical mononucleosis continued to demonstrate the presence of anti-M and anti-I antibodies, but reactions were limited to temperatures of 18 °C or below. The direct Coombs' reaction was now negative.

Because the history suggested cold-induced cyanosis, the patient was given orange-flavored ice sticks on several occasions. After sucking it, the patient's tongue became dark blue, but quickly reverted to its normal pink following withdrawal of the ice stick. Having the patient immerse his hands and feet in ice water produced no change in skin color. One month after discharge, the patient was playing outside in the early evening when his mother noted that his nose had turned blue and that he had a bluish discoloration to his finger tips and around his mouth, which disappeared after he came into the house. Two months after discharge, the patient was seen by his private physician, who noted that the patient's fingers turned blue after he had played on a tiled floor in the office. Since this last episode, the patient has had no other similar occurrences and has been in excellent health.

COMMENT

It has been noted that infectious mononucleosis is unique in the number of diverse antibodies that accompany the disease.[3] The antibody response in infectious mononucleosis includes not only heterophil and Epstein-Barr virus antibodies, but also Donath-Landsteiner cold hemolysins, lymphocytotoxins, anti-T and B-cell antibodies, and smooth-muscle antibodies.[4] In addition, antibodies have been found against human thyroid tissue and rat hepatocytes.[5] The most common antibody with blood group specificity found in infectious mononucleosis is anti-i, which may be present in up to 70% of all cases,[6] although we could not demonstrate it in our patient. Hemolytic anemia is present in 1.7% to 3% of all cases of infectious mononucleosis,[2] and the anti-i antibody has been reported to be responsible for this phenomenon.[7] Hemolytic anemia has also been associated with a positive Donath-Landsteiner reaction.[8]

In one report, auto-anti-N antibody was responsible for decreased RBC survival in mononucleosis.[9] The MN blood group system is itself unusual in the high frequency of autoantibodies found in people without evidence of disease. When normal blood donors are screened using sensitive low ionic strength hexadimethrine bromide polybrene techniques, examples of both anti-N and anti-M antibodies are detected in blood donors whose RBCs contain the corresponding antigen.[10] In some of these cases, the antibody is only transiently present. A recent observation is the increased frequency of auto-anti-N antibodies in hemodialysis patients.[11]

During the acute phase of infectious mononucleosis, cold-sensitive autoantibodies have been detected in 8% to 70% of all cases.[12] Both the anti-M and anti-I antibodies in our patient react at low enough temperatures to be implicated in the acrocyanosis observed on exposure to cold. A possible mechanism for these observations is that "...as blood flows through the capillaries of the skin and subcutaneous tissue, the temperature of the blood falls to as low as 28 °C if the ambient temperature is low. If the cold antibody is active at these temperatures, it agglutinates the cells, and fixes complement. The agglutination obstructs the circulation and results in acrocyanosis.[11,13]

Six months following cessation of clinical symptoms, presence of the anti-M antibody was still easily demonstrable, although presence of the anti-I autoantibody was less clearly shown. Persistence of the acrocyanosis in this patient may have been in part related to the continued presence of the anti-M antibody. Studies were not done to prove whether the autoantibodies resulted in an actual decrease in RBC survival. However, there was no clinical or laboratory evidence that the RBC survival was impaired.

John J. Murray, MD, referred the patient.

Accidental Ingestion of Vacor Rodenticide

The Symptoms and Sequelae in a 25-Month-Old Child

Dana Johnson, MD; Paul Kubic, MD; Carolyn Levitt, MD

• A recently introduced rodenticide containing N-3-pyridylmethyl N′-p-nitrophenyl urea (PNU), Vacor, was accidently ingested by a 25-month-old child, resulting in acute vomiting, lethargy, seizures, and hypoglycemia, as well as chronic evidence of autonomic and peripheral neuropathy and glucose intolerance. Treatment with niacinamide (nicotinamide), may have been of benefit since all problems were resolved within three months of ingestion. This agent (PNU) is remarkably similar chemically and toxicologically to alloxan and streptozocin, both potent beta-cell toxins. These similarities are not only important in regard to the antidote for PNU, but they also suggest that the toxin may cause long-term endocrinologic, neurologic, and oncologic problems.

(*Am J Dis Child* 134:161-164, 1980)

Accidental ingestion of household chemicals is a common occurrence in early childhood. This report describes the case of a child who ingested Vacor, a recently introduced rodenticide (DLP-787, 2% bait; DLP-787, 10% house mouse tracking powder), manufactured by the Rohm and Hass Company, Philadelphia. Vacor contains N-3-pyridylmethyl N′-p-nitrophenyl urea (PNU), a substance chemically related to alloxan and streptozocin.[1] Both alloxan and streptozocin are potent beta-cell toxins and have been used for a number of years to induce experimental diabetes in animals and to treat islet-cell carcinomas. Apparently, PNU has similar adverse effects on beta cells since it produces hyperglycemia in rats and diabetes mellitus in humans.[1-2-3]

Since the introduction of Vacor in 1975, reports of ingestions by adults in suicide attempts have been documented, but, to our knowledge, this is the only well-documented ingestion reported in the pediatric age group. This agent not only has substantial acute problems associated with its ingestion, but also has the potential for causing definite long-term sequelae.

REPORT OF A CASE

A 25-month-old boy arrived at the St Paul (Minn) Children's Hospital Clinic with symptoms of vomiting, lethargy, anorexia, and a major motor seizure. The child had been in good health, except for a three-day history of rhinitis, until the night before admission when he vomited five times prior to going to bed. The next morning, his mother reported he was stuporous and anorectic and he vomited once again. Shortly thereafter, he had a major motor seizure lasting about two minutes and was brought immediately to the hospital. During the admission interview, the parents expressed concern that the child may have ingested Vacor, which they had placed around the house. The patient's cousin later admitted to feeding the child an unknown amount of the substance on a piece of gum.

The patient's medical history was unremarkable except for a seizure with fever at the age of 16 months. Metabolic and neurologic evaluations at that time showed no abnormalities. Family history showed a deceased maternal grandmother who had juvenile onset diabetes mellitus.

On admission, the patient was lethargic, inconsistently responsive, but generally arousable to vigorous stimuli. His vital signs included the following: weight, 14.9 kg; temperature, 36.2 °C; pulse rate, 104 beats per minute; respirations, 26/min; and blood pressure, 82/50 mm Hg. There was no evidence of trauma. His neck tone was normal; the cranial nerves were normal and the fundi were clear. There was a mild ptosis bilaterally and his face appeared slightly puffy. The pupils were generally constricted but dilated when the patient was aroused. Deep-tendon reflexes were symmetric but brisk, and both Babinski's signs were positive. The remainder of the results of the physical examination were within normal limits except for a mild rhinitis.

At the time of his arrival to the clinic, the seizure had stopped, and he was lethargic. He was given 90 mg (6 mg/kg) phenobarbital intramuscularly, and gastric lavage was performed immediately. A blood sample was obtained and an intravenous (IV) infusion of dextrose and an electrolyte solution was started. Niacinamide (100 mg) was given intravenously. The blood sample drawn at 10 AM, prior to the IV infusion gave the following results: blood glucose, 18 mg/dL with low serum ketones (1+); serum sodium, 145 mEq/L; potassium, 4.5 mEq/L; calcium, 5.8 mEq/L; BUN, 15 mg/dL; SGOT, 35 mU/mL; serum ammonia, 51 μg/dL; and venous pH, 7.37 with a P_{CO_2} of 37.7 torr. The complete blood cell count showed a hemoglobin level of 11.3 g/dL and a WBC count of 11,700/cu mm, with 80% neutrophils, 12% lymphocytes, and 8% monocytes. Blood lead level was 0.028 mg/dL (normal, less than 0.040 mg/dL). Tests for heavy metals showed no evidence of mercury, arsenic, antimony, or bismuth in the urine. The EEG done shortly after admission showed multifocal spikes consistent with a seizure disorder. In the hour after admission to the hospital, he continued to have noticeable fluctuation in his level of consciousness. At 2 PM, when the presence of hypoglycemia was reported, he was immediately given 20 mL of 25% dextrose solution. He showed a gradual return to a more wakeful state within the next 40 minutes and subsequently had only one further episode of unresponsiveness and fixed gaze. The blood glucose level, just prior to the dextrose infusion, was 46 mg/dL; and 1¼ hours later, it was 102 mg/dL. He was given 100 mg of niacinamide intravenously at 3 PM and again at 9 PM, at which time the blood glucose level was 255 mg/dL. Four hours later, it was 155 mg/dL.

The child had no seizures the next day. Niacinamide (50 mg) was given intravenously every four hours. The blood glucose level remained in the range of 175 mg/dL but increased to 350 mg/dL on the third day and to 380 mg/dL by the fifth day. Urinary glucose levels fluctuated from trace to 4+ with small to large acetones

initially, followed by negative urine acetone values. Serum acetone tests always remained negative.

On the third day, IV feedings were discontinued, and oral doses of 50 mg of niacinamide were given four times a day. The child had been eating, but he experienced liquid stools during that day. On the fourth day, his mother reported that he seemed to have pain. Examination showed him to be listless and fussy. When sitting up, he was unsteady and attempted to stiffen his extremities. The pain seemed to increase on movement. His eyes were watering, his respirations were noisy, and he had a poor cough. His abdomen was distended, and there was muscle guarding. His SGOT level, which had increased from 35 mU/mL on day 1 to 116 mU/mL on day 3, now was 24 mU/mL. A prothrombin time of 15.5 s (control, 12.1 s) and a partial thromboplastin time of 83 s (normal, 50 s) were reported. Serum amylase level was 169 units/dL (normal, 60 to 160 units/dL).

The next day, his abdomen was firm, tender to palpation, and tympanitic to percussion. He no longer was having loose stools but did not have control of bowel or bladder function. He had previously been toilet trained and was able to void in the urinal. Abdominal roentgenograms showed ileus. A chest roentgenogram showed a patchy pneumonitis of both lower lobes. Intravenous feedings were reinstituted, 50 mg niacinamide was administered intravenously every six hours, and 600,000 units of aqueous penicillin G potassium were given every six hours intravenously. On the eighth hospital day, his mother reported he laughed and talked for the first time since admission. However, we found him to be only slightly more alert and still lethargic and irritable. His abdomen was softer, with minimal muscle guarding.

By the 11th hospital day, he had leg pain. During examination, he resisted manipulation of both legs and refused to stand. The severity of pain seemed to vary from one leg to the other. He had not stood since the time of admission. Roentgenograms and a bone scan were done of both legs to rule out an infectious process. Both studies were normal. Electromyography of the boy was refused by the mother. Neurologic examination showed reflexes to be brisk and symmetric, with intact sensation.

The pneumonitis cleared by the 13th day. He continued to be lethargic and irritable and he was in pain. He was discharged on the 15th day and was still unable to stand or walk. At this time, he had glucosuria (3 to 4+) but no ketonuria. He was on a regular diet, and quantitative urine glucose tests done near the end of the hospital stay showed the patient to be spilling approximately 15% of the dietary carbohydrate intake. Insulin injection therapy was not given during the hospital stay nor after discharge. An EEG done on the 14th hospital day was normal. His mother was instructed to give him 50 mg of niacinamide orally every six hours to be continued for the next four weeks.

One week after discharge, the patient still seemed to be in pain. He refused to walk and would not stand without support, but would slowly move his legs. He consistently had glucosuria (3+) but no ketonuria. A single blood glucose value was 321 mg/dL. A week later, a glucose tolerance test result was normal, as were simultaneous insulin levels. The child continued to have leg pain.

Three weeks after discharge from the hospital, the patient was talking, but his gait was unsteady and wide based. His eyelids were still droopy and he had not recovered bowel or bladder control. Tests showed negative urine glucose values.

RESULTS

The patient was then lost to follow-up until he was brought to the emergency room about three months later with a grand mal seizure associated with a temperature of 41 °C. Tests showed normal blood glucose and serum electrolytes levels, and there was no evidence of glucosuria or ketonuria. When fully examined the next day, there was no evidence of leg pain or gait abnormalities. The ptosis had resolved and he had regained control of his bowel and bladder function. Niacinamide therapy had been discontinued. Further examinations have not been done though his mother reports that he seems entirely normal.

COMMENT

Toxic Effects and Clinical Symptoms

This PNU is a potent toxin that causes death or severe sequelae in a high proportion of individuals who ingest it.[1,4,5] As ingestions of rodenticides containing PNU become more frequent in children, it is imperative that physicians familiarize themselves with the symptoms caused by the toxin.

The acute clinical symptoms of intoxication seem to be vomiting, alterations in the state of consciousness with possible seizures, and disturbances in glucose homeostasis. The symptoms are similar to those associated with ingestions of other drugs such as salicylates and oral hypoglycemic agents or to the symptoms of metabolic disturbances such as diabetic ketoacidosis. These clinical and laboratory manifestations are similar to the abnormalities produced in humans and laboratory animals from the closely related compounds streptozocin and alloxan. Nausea and vomiting have been reported in up to 75% of patients for whom streptozocin was being used to treat malignant neoplasms.[6] Disturbances in blood glucose levels seem to be almost identical to the responses seen in laboratory animals given toxic doses of either drug.

Both streptozocin and alloxan produce a triphasic response after injection.[7] The first phase is a brief period (one to four hours) of hyperglycemia. The degree of hyperglycemia seems to be dependent on liver glycogen concentration and is accompanied by low circulating immunoreactive insulin (IRI) levels. The second phase is a period of severe hypoglycemia lasting up to 48 hours. Levels of IRI are notably elevated during this period, probably due to massive beta-cell necrosis and release of stored hormone. Experimental animals convulse and often die during this period. The third phase is a period of chronic hyperglycemia that may be of long, if not permanent, duration. The severity and length of this period is dependent on the number of beta cells destroyed by the drug. It has not been shown that PNU produces this triphasic response, but our patient demonstrated severe hypoglycemia followed by chronic hyperglycemia. If he had been examined immediately after ingestion, he may indeed have been hyperglycemic. Thus, patients may have a wide variation in serum glucose levels depending on the time interval between ingestion and report of the incident. The documentation of the entire triphasic response may be diagnostic of PNU intoxication, but laboratory tests at any one point during the patient's acute course may not provide a definitive diagnosis. Because of this, it is imperative that PNU ingestion be considered when any child has vomiting, alterations in consciousness, and aberrations in glucose homeostasis.

In addition to the chronic diabetes mellitus of variable duration, PNU

has also been reported to cause autonomic dysfunction in the form of hypothermia, hypotension, dysphagia, dystonia, and bowel and bladder dysfunction. Motor and sensory neuropathies, and possible inappropriate antidiuretic hormone secretion are also described.[1-5] In our patient, the neurotoxic effects of PNU led to ileus, hypotonia, ptosis, mild facial paresis, and painful paresthesias. The paresthesias and fecal retention noted in our patient persisted for several weeks.

Effects on additional organ systems have not been reported in humans, but both streptozocin and alloxan have been reported to be nephrotoxic. Streptozocin has been shown to cause varying degrees of renal dysfunction such as Fanconi's syndrome, azotemia, and even anuria after treatment.[6-8-9] Alloxan is known to produce similar transient effects in animals.[10] There is also evidence that both drugs in high doses cause liver damage. Streptozocin has been reported to cause damage to the exocrine pancreas, leukopenia, and thrombocytopenia.[6-11-12] This may explain the transient, mild increase in both serum transaminase and amylase levels noted in our patient.

Mechanism of PNU Toxicity

The exact mechanism of PNU toxicity is not known, but preliminary evidence indicates niacinamide antagonism.[2] It seems to work in a manner similar to streptozocin. Streptozocin (glycopyranose, 2-deoxy-2 (3-methyl-3-nitro soureido)-D-) has been shown to exhibit antibiotic,[13] oncolytic,[6] and oncogenic[14] activity in addition to its diabetogenic potential.[15] In animals given toxic doses of streptozocin, examination of the beta cells by electron microscopy showed dilated endoplasmic reticulum, swollen mitochondria, and partial or complete degranulation of the cells.[16-17] Schein et al[16] and Schein and Loftus[18] have shown that this effect is probably mediated through the drug's specific effect on reducing intracellular synthesis of NAD and NADH (oxidized and reduced niacinamide adenine dinucleotide). One IV dose produces a 24-hour depression of both NAD and NADH concentrations in rat liver, with a return to normal concentrations by 48 hours. This effect on NAD and NADH, as well as on beta-cell ultrastructure, could be prevented by the injection of 500 mg/kg of niacinamide intraperitoneally (IP) ten minutes prior to the treatment with streptozocin. Niacinamide also seems to prevent the development of diabetes. Small serial administrations of niacinamide either IP or orally during a 24-hour period seemed to be more beneficial than a single intraperitoneal injection. This probably relates to the fact that detectable levels of streptozocin remain in rat liver for 20 hours after a single injection[18] whereas detectable niacinamide levels are only present in rodent liver for approximately 16 hours after a single intraperitoneal dose.[19]

Niacinamide seems to be the specific antagonist of choice for dealing with the effects of streptozocin. N'-methyl niacinamide, niacin (nicotinic acid), and L-tryptophan, all precursors of NAD, have no effect on either preventing streptozocin-induced depression of liver nucleotide levels or preventing the development of diabetes mellitus.[16-20] The cause for this specific effect was investigated by Tjalve and Wilander,[20] who determined that there is a relationship between the ability of the NAD precursors to be taken up by the pancreatic islets and their ability to prevent streptozocin diabetes. They found that only niacinamide was accumulated to any extent within the islet whereas L-tryptophan and niacin were not.

Other than the antagonism of PNU by niacinamide, and preliminary indications that biotransformation is important in its detoxification,[2] little is known regarding its pharmacology in animals and no data are available in humans. More is known about streptozocin,[21-22] though the pharmacology of the two drugs may not be directly comparable despite their chemical similarities.

When streptozocin (1.5 g/kg) is given by IV bolus injection, the pharmacokinetics fit a two-compartment model with the central compartment having a volume compatible with the plasma and RBC volume, and the peripheral compartment corresponding to the volume of the extracellular fluid. There is a rapid transfer to the peripheral compartment from the central compartment, but there is little in the reverse direction. The biologic half-life of the drug is 40 minutes, both in serum and tissue. The precise metabolism of streptozocin has not yet been completely determined, but the drug has several metabolites, some of which remain in tissue for several days. Urinary excretion of streptozocin or its metabolites is low (11% to 15%). Most is excreted within the first six hours after IV injection.

Treatment Regimen

The scarcity of concrete data on the pharmacology of PNU in humans makes recommendation of a dogmatic treatment regimen impossible. Emesis is recommended if the ingestion is recent enough to expect the chemical to still be in the stomach. The advisability of activated charcoal and/or cathartic administration has not been studied, but it is recommended on an empiric basis. There are no data to suggest that ion trapping and forced diuresis are of benefit. No data exist to suggest that dialysis or hemoperfusion are efficacious in treating PNU ingestions.

Niacinamide seems to be the most specific antidote for PNU ingestion. Niacinamide has been used as an antidote in rats given toxic doses of PNU.[2] It was most effective when given within one hour of ingestion. Niacin did not seem to be as effective in preventing toxicity, but rats fed high levels of L-tryptophan in their diets did seem to be protected. There is also evidence that niacinamide antagonism may play a role in the development of neurologic symptoms.[23]

With the data presently in the literature, it is impossible to predict the likelihood of permanent damage caused by PNU since dosage, age, and interval between ingestion and treatment have varied so greatly among affected individuals. Therefore, it would not be prudent to withhold treatment until the development of clinical symptoms or laboratory evidence of PNU toxicity, since permanent damage can occur by that time. We believe strongly that all individuals whose conditions are suggestive of PNU ingestion should immediately be started on a regimen of niacinamide in view of the low toxicity and potential benefit from this compound. The

recommended dosage is 50 to 100 mg niacinamide intravenously every six hours for two to three days, followed by the same dosage of niacinamide taken orally for two to four weeks.

Long-term sequelae in the form of glucose intolerance and/or neurologic dysfunction have been frequent among the survivors of acute intoxication.[1,3,5] Some individuals will have permanent insulin-dependent diabetes and others will have no carbohydrate intolerance at all. Another group, however, may have an intermediate course as our patient did, having an acute episode of hyperglycemia followed by total resolution. These individuals obviously have sustained damage to their beta cells as demonstrated by their hyperglycemia. This situation is not unlike juvenile onset diabetics who begin with an active, insulin-deficient state that improves transiently only to gradually deteriorate as residual beta-cell function is lost. These individuals who seem to have recovered may eventually lose their remaining beta-cell function and experience true insulin-dependent diabetes. Close follow-up of these individuals is obviously necessary.

Even more ominous than the specter of chronic diabetes mellitus is the possibility that PNU may share the oncogenic potential of streptozocin. Streptozocin is closely related to the carcinogenic nitrosoamines and, as such, has been reported to cause renal neoplasms in a high percentage of treated animals.[14] Rakieten et al,[24] in studying the ability of niacinamide to prevent the development of these tumors, found a decrease from 77% to 18% of tumor-positive animals when the animals were treated with niacinamide both before and three hours after their dose of streptozocin.

Treatment with niacinamide, at least in rats, does not seem to be completely without risk. Although treatment seems to prevent the development of acute symptoms and decreases substantially the incidence of renal tumors, niacinamide acts as a cocarcinogen in producing islet cell adenomas. These tumors occur in extremely high proportions of treated animals,[25-27] after a rather lengthy latent period of 19 to 24 months. Rats bearing these tumors, that seem to be benign, well-encapsulated adenomas,[28] experience and often die with profound hypoglycemia.

Schoental[29] has described similar tumors in rats given heliotrine, a monoester pyrrolizidine alkaloid, and niacinamide. Heliotrine apparently exerts its toxic effect in a manner similar to streptozocin by interfering with intracellular NAD levels.[30,31] Schoental's work suggested that pretreatment with niacinamide lessened some of the drug-caused damage to the liver but seemed to induce islet-cell tumors in 50% of the long-term survivors. In addition, a transitional cell papilloma of the bladder, a hepatoma, and an interstitial-cell testicular tumor were found in treated animals.

It is obviously difficult to compare the precise oncogenic potential of compounds, even if they are closely related. Similar effects of PNU may not be observed, and even if the drug is carcinogenic in humans, the affected organs may be different. Evidence is compelling, however, that in certain rat neoplasms, common metabolic pathways involving NAD metabolism may be involved in both the acute toxic effects and the delayed oncogenic sequelae; these are the same metabolic pathways that PNU seems to affect. Close follow-up observation of affected individuals is obviously indicated.

Rothmund-Thomson Syndrome With Severe Dwarfism

Judith G. Hall, MD; Roberta A. Pagon, MD; Kathleen M. Wilson

• Two patients had severe dwarfism and limb anomalies, but also had other clinical characteristics of the Rothmund-Thomson syndrome, including characteristic skin changes, abnormal hair growth, sensitivity to sunlight, defective nails and teeth, and juvenile cataracts. We emphasize that this diagnosis should be considered in any patient with extremely short stature, associated skeletal anomalies, and an early onset of typical cutaneous changes.

(*Am J Dis Child* 134:165-169, 1980)

Rothmund-Thomson syndrome, or poikiloderma congenitale, is a rare autosomal recessive disorder characterized by the infantile onset of dermal atrophy associated with telangiectasia, hyperpigmentation, and depigmentation. Additional findings are sparse hair or alopecia, sensitivity to sunlight, dystrophic nails, and defective dentition. More than 50% of the patients have juvenile cataracts, small hands, hypogonadism, and short stature. Congenital skeletal anomalies, primarily of the forearms and hands, are less common, but they have been observed in about 5% of the reported cases. We describe two patients with severely short stature, limb anomalies, and other clinical findings suggestive of the Rothmund-Thomson syndrome. These patients illustrate that in some cases features that are usually considered minor may predominate over the dermatologic manifestations.

REPORT OF CASES

CASE 1.—This infant (Fig 1) weighed 1.6 kg and was 40 cm long at birth. She was delivered by breech after a 36-week gestation to a 29-year-old gravida 4 , para 4, abortus-0 mother and a 37-year-old unrelated father. There was no family history of congenital anomalies, abortions, stillbirths, or neonatal deaths. She required hospitalization for three months after birth for feeding difficulties, but had no respiratory problems. Skeletal abnormalities noted at birth were bilateral absence of the first metacarpal and thumb and absence of the left radius and hypoplasia of the right radius, which resulted in the radial deviation of both hands. The other fingers were normal, but there was shortening of the first toes bilaterally. Postnatal growth was poor, and she weighed only 3.2 kg at 7 months of age. She had a striking craniofacial disproportion with absence of the supraorbital ridges and a large anterior fontanelle, which suggested hydrocephalus

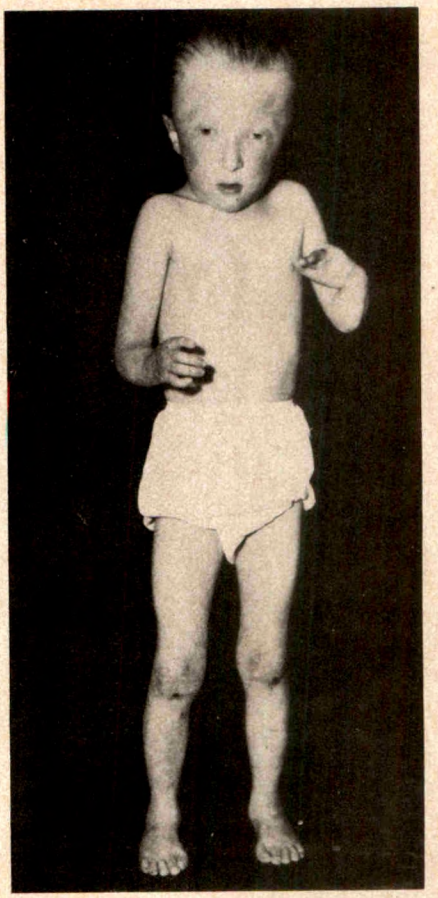

Fig 1.—Patient 1 at age 5 years, 11 months. Typical cutaneous changes with dermal atrophy and hyperpigmentation are present on face and extensor surfaces of limbs. Absence of thumbs and left radius and hypoplasia of right radius are seen.

to some observers. Many other "soft spots" were present on the patient's head, apparently representative of areas of thin calvaria.

Freckles over her trunk, limbs, and face were present at birth. The freckles were exacerbated by the sun at about 1 year of age, and redness, telangiectasia, and atrophic areas appeared later. Sweating was normal. Sun-exposed skin tanned normally despite a tendency to sunburn. Eyebrows and eyelashes were absent from birth. Fingernails and toenails tended to grow slowly. At age 7 years, several carious teeth were extracted. Menarche was at age 12 years, with normal secondary sexual development. She was of normal intelligence and graduated from high school at the usual age with average grades.

Despite the limb anomalies, she had no orthopedic problems until 7 years of age, at which time her feet and knees appeared internally rotated. Roentgenograms showed bilateral absence of the patella, a straight spine, and metatarsus adductus with apparent talocalcaneal fusion and talonavicular fusion on the right. The distal femoral and proximal tibial epiphyses were abnormal, and there was lateral displacement of the tibiae with a mild valgus deformity of the knees and bilateral posterior subluxation of the proximal tibia. The femoral heads and hips were normal. Bilateral supracondylar femoral osteotomies performed at age 9 years failed to correct the flexion and valgus deformities, and osteoporosis of the long bones of the leg subsequently occurred. At age 15 years, she had a Charnley compression arthrodesis of the left knee to fuse the joint and correct the residual flexion deformity and posterior subluxation of the tibia.

The patient was first examined by us at age 19 years. Her height was 113.8 cm, her weight was 24.5 kg, and her occipitofrontal circumference was 44.8 cm. Extensive skin involvement included a "freckled" appearance over most of the body that was interspersed with areas of atrophy and hypopigmentation with telangiectasia predominantly over extensor surfaces of her limbs. Her facies was distinctive (Fig 2) with a high, flat forehead, a lack of supraorbital ridges, and a long, thin, prominent nose. Despite a history of normal scalp-hair growth, the hair was thin in places, and her eyebrows and lashes were completely absent; her eyes were normal. Her mouth was small, and the teeth were carious. The mandible was small and receding. Skeletal changes included bilateral absence of the

Fig 2.—Patient 1. Characteristic facies includes high forehead, lack of supraorbital ridges, long nose, and sparse eyebrows and eyelashes.

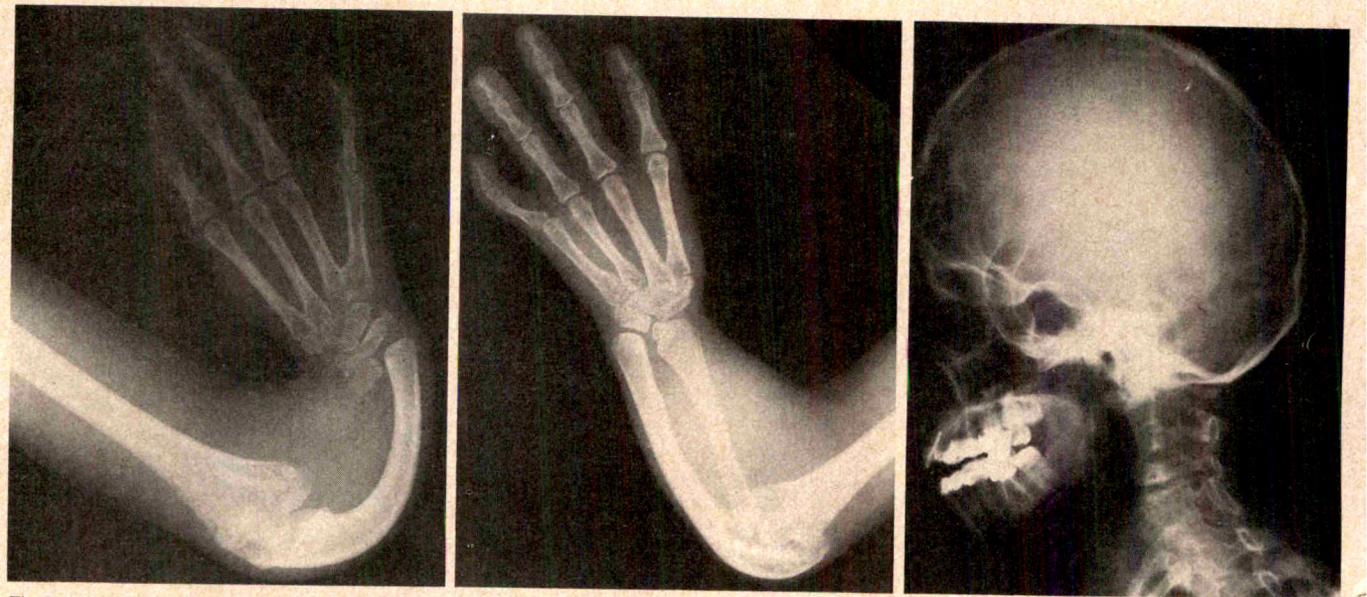

Fig 3.—Patient 1 at 19 years of age. Left and Center, Note bilateral absence of first metacarpal and thumb, small second and fifth middle phalanges, fusion of fourth and fifth metacarpals on left, absence of left radius, and hypoplasia of right radius. Right, Skull appears microcephalic, with increased markings and flat angle at base. Cervical vertebrae are irregular and fused.

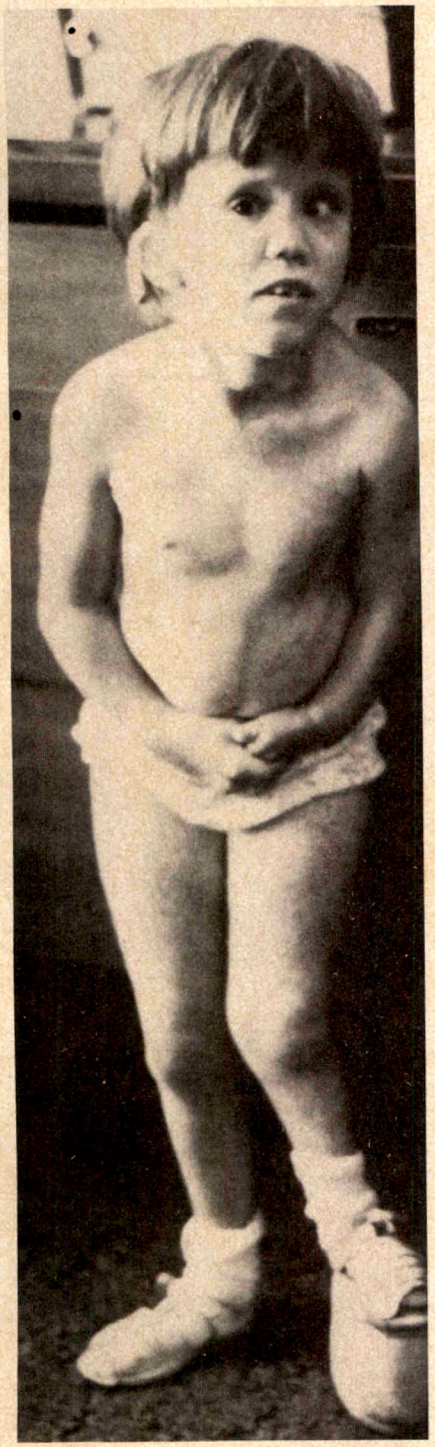

Fig 4.—Patient 2 at 11 years of age. Note proportionate short stature with radial hypoplasia and short leg on left, small nose, strabismus, asymmetric chest, and irregular areas of dark pigment.

Fig 5.—Patient 2 has dermatologic changes with irregular pigment and areas of hypoplastic skin.

first metacarpal and thumb, absence of the left radius, and hypoplasia of the right radius (Fig 3). The femur was displaced medially. The fibula and tibia had narrow diaphyses. Her skull appeared microcephalic, with increased markings and a flat angle at the base. The cervical vertebrae were irregular and fused (Fig 3). The lumbar vertebrae were relatively tall and tubular, with mild irregularities and narrow disk space. Increased lumbar lordosis was present.

CASE 2.—A female infant (Fig 4) was born at term weight, 2.2 kg, length, 43.8 cm, the product of the first pregnancy of 25-year-old unrelated parents. The mother was 168.8 cm tall, and the father was 190.0 cm tall. Prior to pregnancy, the mother had erythema nodosum that continued into the first trimester. In addition, the mother had a tonsillectomy under general anesthesia during the first month of pregnancy. After the operation, she received oral doses of codeine for one to two weeks.

At birth, the patient was noted to have a saddle nose and bilateral cataracts. She had multiple tiny hemangiomata over her face, trunk, buttocks, extremities, and one palm; her skin was otherwise normal, and the hemangiomata disappeared during the first year of life. Freckles and cafe-au-lait spots began to appear at age 4 years without preceding erythema or sun sensitivity. There was no history of blistering, but atrophic areas of skin gradually appeared.

Roentgenograms at 3 months of age reportedly showed deformities of the vertebrae and shortening of the metacarpals and metatarsals, fibula, and radius. At 5 months of age, asymmetric disproportionately short stature with shortening of the left leg and left arm with bilateral asymmetric brachydactyly was noted. Epiphyses were mottled and irregular, and the diagnosis of Conradi-Hünermann syndrome was considered, but no stippling of the epiphyses was seen at that time or on roentgenograms obtained at 1 year of age. Shortening in the left leg was primarily accounted for by the tibia, and the second, third, and fourth toes were asymmetrically short. Asymmetry of leg length required shoe lifts from age 3 years. At age 6 years, kyphoscoliosis of the thoracic spine was treated with a Milwaukee brace.

Cataracts were surgically extracted at 8 months of age; the remainder of the findings of her eye examination were normal, except for strabismus. At 2½ years of age she was found to have sensorineural deafness of moderate severity, a 60- to 80-dB loss bilaterally. During early infancy, she occasionally had lingering chest colds, but otherwise was healthy throughout childhood.

She had a severe growth deficiency: a height of 53.8 cm and weight of 4.1 kg at 4 months of age, 63.8 cm and 6.8 kg at 2½ years, and 72.5 cm and 7.3 kg at 5½ years. Tooth eruption was delayed so that at age 15 months she had only three teeth.

Motor development was delayed; she neither sat nor pulled herself to a standing position until after 1 year of age; she pulled herself to a standing position by 3 years of age, but was walking only poorly at 5 years of age. At age 9 years she was in special education classes, but was functioning at an age-appropriate level in many areas.

On physical examination at 9 years of age she was 82.5 cm tall and had patchy depigmentation and areas of marbled hyperpigmentation on her trunk (Fig 5). Patches of dry and atrophic skin were intermixed with hyperpigmented macules on the extensor surface of the arms and legs. Except for patches of alopecia, the scalp hair showed normal growth and texture. Eyebrows were sparse, but the eyelashes were normal. She had frontal bossing, a prominent venous pattern of the forehead, and midface hypoplasia with a flattened nasal bridge and upturned nasal tip. The mandible was small. The primary teeth were dysplastic, with only one

secondary tooth present. Her teeth were widely spaced and irregular. Her voice has always been high pitched, with a squeaky quality. Her ears were small and thickened.

The left leg was 8 cm shorter than the right, with marked bilateral genu valgum. There was decreased extension of both elbows; her right arm appeared to be normal, but her left radius was hypoplastic, and the hand was radially deviated. Kyphosis of 90° in the upper thoracic spine was combined with a moderate degree of scoliosis.

When seen again at 11 years of age (Fig 4), she was 90.0 cm tall and weighed 11.4 kg. Her head was at less than the third percentile for her age (occipitofrontal circumference, 47.5 cm), although it appeared proportionate for her height. Except for several graying scalp hairs, there was no significant change in the findings of her physical examination. Chromosome studies with R-banding from peripheral blood and a skin fibroblast culture were 46, XX without breaks, gaps, or marker chromosomes detectable; 180 metaphases were studied.

No relatives are similarly affected; however, the patient's mother and maternal grandmother both have angiokeratoma corporis diffusum that developed during pregnancy. Neither of them has other pigmentary problems. The patient's only sibling, a brother, is unaffected and healthy.

Characteristic Abnormalities of Rothmund-Thomson Syndrome

Feature	Frequency of Occurrence,* % (No.)	Presence	
		Case 1	Case 2
Skin changes: atrophy, erythema, pigmentation, telangiectasia	100 (46)	Yes	Yes
Female	72 (33)	Yes	Yes
Short stature	54 (25)	Yes	Yes
Juvenile cataracts	52 (24)	No	Yes
Sparse or absent eyebrows and eyelashes	50 (23)	Yes	Yes
Skeletal anomalies	39 (18)	Yes	Yes
Skin sensitive to sunlight	35 (16)	Yes	No
Hypogonadism	24 (11)	No	No†
Dystrophic nails	24 (11)	Yes	No
Defective dentition	15 (7)	Yes	Yes

*Indicates that the percentages are from 46 cases reviewed by Taylor[6] in 1957.
†Indicates that the patient is prepubertal.

COMMENT

Rothmund-Thomson syndrome is a rare autosomal recessive disorder that was first described by Rothmund[1] in 1868 as an association of "cataracts. . .with a peculiar skin degeneration" and later by Thomson in 1923[2] and 1936[3] as poikiloderma congenitale (literally, "congenital variable skin"). Its clinical characteristics vary greatly, but the major features are the characteristic dermatologic findings often associated with cataracts, short stature, hypogonadism, skeletal anomalies, and typical facies (Table 1).

The skin changes are summarized by Rook et al.[4] They emphasize that the first dermal manifestations typically appear between 3 and 6 months of age, but occasionally are present at birth or appear as late as 2 years of age. The initial lesions are usually erythematous plaques, reticular erythema, or diffuse erythema of the face (especially the cheeks), with gradual involvement of the dorsum of the hands and forearms and the extensor surfaces of the legs, thighs, and buttocks by the end of the second year. Sun-exposed skin is typically more severely involved, while the trunk and flexor aspects of the limbs are usually spared. The palms are never involved. Sun sensitivity, which was seen in all cases, often causes bullous eruptions with minimal exposure and diminishes with age.

The erythematous stage is followed by the chronic poikilodermatous stage, which consists of dermal atrophy, telangiectasia, depigmentation, and hyperpigmentation in a characteristic distribution over the extensor surfaces of limbs. Typically, multiple small, pale, atrophic circumscribed macules are enclosed by a reticulate pattern of dull red telangiectasias. "Smudges" of brown pigmentation develop later in the areas of atrophy and telangiectasias and may extend over uninvolved skin, especially on the neck and trunk. Macular areas of depigmentation without atrophy are also seen. In general, the telangiectasias predominate on the face and hands, while the pigmentary changes involve the limbs and trunk, where they may be the only abnormality. Xerodermatous scaling of the skin of the extremities occurs in time, as well as hyperkeratosis of the knees and elbows.

When the chronic stage has been attained in childhood, the skin lesions usually persist without change throughout life, although keratoses of the face, hands, and feet and carcinomatous degeneration may occur at a later age in those individuals who are especially sensitive to the sun. Both of our cases showed typical skin changes, with atrophy, telangiectasias, and hyperpigmentation of sun-exposed areas, especially the face and cheeks and the extensor surfaces of the arms and legs. Case 1 is unusual in that the pigmentary changes, which appeared as freckles over the trunk, limbs, and face, were present at birth. Patient 2 exhibited multiple scattered hemangiomata at birth (which later disappeared) and typical hypo- and hyperpigmentation that began at 4 years of age without a prior erythematous stage.

In this disorder, the scalp hair is usually sparse and fine, but the spectrum ranges from normal hair to total alopecia. There may be a sudden partial or total loss of scalp hair and eyebrows and eyelashes in early childhood. Body hair is absent in the affected skin areas. The nails range from normal to dystrophic or atrophic, and some patients have faulty dentition with microdontia, failure of eruption, and carious tendencies. Both of our patients had fine hair with sparse areas, deficient eyebrows and eyelashes, and carious teeth.

Microcephaly characterized by a triangular, bird-like facies and a high forehead, frontal bossing, and saddle nose that is reminiscent of congenital lues is typically seen. Our patients both have the high forehead and triangular facies. Patient 1 had no supraorbital ridges and a thin, prominent

nose. In Case 2, the frontal bossing, flat nasal bridge, and saddle-nose deformity predominate.

Bilateral cataracts appear suddenly between the ages of 4 and 7 years and occur in 40% to 50% of the reported cases. Patient 1 had no eye anomalies, and patient 2 was unusual in that the bilateral cataracts were congenital. Other eye changes are significantly less common and include degenerative changes of the cornea,[5] microphthalmia with optic atrophy and severe myopia,[3] and colobomata.[6]

• Hypogonadism characterized by small or cryptorchid testes in males and scanty, irregular menses in females and reduced fertility may occur in as many as 25% of cases. Patient 1 experienced normal puberty, and patient 2 is too young for such a determination.

Mental retardation has been reported, but is uncommon. Patient 1 is of normal intelligence; patient 2 had slow developmental landmarks, but the visual and hearing deficits may partially account for her adaptive difficulties.

Short stature with small hands and feet and stubby fingers and toes is estimated to occur in 50% of the patients with Rothmund-Thomson syndrome, although it actually seems to be almost an invariable finding. Less common is severe dwarfism, which has been reported by several authors: Rothmund[1] described a 121-cm tall woman in 1868; Jackli,[7] a 111-cm tall girl, 12 years of age, in 1939; Seefelder,[8] a 121-cm tall man in 1935; Thannhauser,[9] a 149-cm tall, 20-year-old man in 1945; and Castel et al,[10] a 86-cm tall, 10-year-old child in 1977. Our two cases (a 113.8-cm tall, 19-year-old girl, and a 90.0-cm tall, 11-year-old-girl) are additional examples of Rothmund-Thomson-syndrome patients with extreme growth failure. The growth failure in our patients was of prenatal onset, with deficiencies in both birth weight and length. These deficiencies are, in fact, reported but not emphasized in most of the previously reported cases. Sufficient data to construct growth curves or predict adult height are not available from the reported cases.

The absence of the metacarpals and phalanges of the thumbs bilaterally with reduction deformities of the ulnae and radii[3,4] or total absence of the radii[10] have been described. In addition, one patient[10] had bilateral subluxation of the knees like that of case 1. Unilateral split-hand and split-foot deformities have been described in two patients.[11,12] The kyphosis and scoliosis of case 2 is unique, and skeletal asymmetry is rare.[11]

Osteoporosis, as seen in case 1, and patchy sclerosis and cystic changes of the long bones[5,6] are less common changes, as seen on roentgenograms. Short, stubby hands and feet with short toes are uniformly found, yet roentgenogram documentation is insufficient to further characterize the brachydactyly. Probably less than 5% of the patients have other skeletal anomalies such as the unilateral hypoplasia of the radius and/or ulna with or without absence of the thumb as in case 2 or the bilateral radial aplasia with absent thumbs as in case 1. To our knowledge, the sensorineural deafness of patient 2 has not been undescribed as part of this disorder.

The broad spectrum of clinical features of Rothmund-Thomson syndrome is unexplained. Our patients, who had severe but proportionate short stature and skeletal anomalies, meet all the criteria for the diagnosis of this disorder; however, they are unique in that they have primarily skeletal manifestations with typical, although less striking, skin involvement. We suggest that this autosomal recessive disorder should be considered in any patient with severe growth failure, associated skeletal anomalies. and an early onset of typical cutaneous changes.

This investigation was supported by Gene Center grant GM15253 from the US Public Health Service, by Fellowship Training grant CA-90, and by National Foundation March of Dimes grant 6-44.

William Miller, MD, Thomas Bolton, MD, and David Rimoin, MD provided patient information. Joy Palmer of Shriner's Hospital, Spokane, Wash, did the records search. Lynn Staheli, MD, referred case 2 to us. Leonard Langer, MD, reviewed the roentgenograms. Bonnie McLoughlin and Maxine Covington provided editorial and secretarial assistance.

A Case of Leprechaunism With Severe Hyperinsulinemia

Alan M. Rosenberg, MD; James C. Haworth, MD; G. William Degroot, MD; Cynthia L. Trevenen, MD; Matthew M. Rechler, MD

• This report describes an infant with physical features typical of leprechaunism, including a characteristic facies, hirsutism, and decreased subcutaneous tissue and muscle mass. Intermittent hypoglycemia and severe hyperinsulinemia were documented. The patient's insulin was normal in molecular size and biological activity, but its binding to the patient's cultured fibroblasts was profoundly decreased. Insulin antibodies were not present. A literature review has been undertaken to clarify further the clinical, metabolic, and pathological characteristics of this condition.

(*Am J Dis Child* 134:170-175, 1980)

Since the first report of leprechaunism in 1948, we are aware of descriptions in the literature of 24 patients with features typical of this syndrome.[1-22] Infants with leprechaunism fail to thrive and have decreased subcutaneous tissue and muscle mass, a characteristic facies, enlarged genitalia, and hirsutism. Abnormalities of carbohydrate metabolism have been common. This report describes an infant with physical features typical of leprechaunism. Intermittent hypoglycemia and pancreatic islet cell hyperplasia were present. Additional striking features were sustained, severely elevated serum insulin levels and profoundly reduced insulin binding to the patient's cultured skin fibroblasts.

REPORT OF A CASE

The patient, a Canadian Indian male infant, was the third child of parents who were first cousins once removed. His 28-year-old father, 25-year-old-mother, and two older sisters were reportedly healthy. Because the patient's ancestors reside in remote areas, a detailed family history could not be obtained. A maternal first cousin who had unusual facial features was said to have died of starvation at 8 days of age. One of the maternal grandmother's siblings died in infancy and reportedly had unusual physical features. None of the family members was available for detailed clinical or laboratory evaluation. A normal labor and precipitous vaginal delivery followed a full-term, uncomplicated pregnancy during which there was no known teratogenic exposure. There was no history of maternal gestational diabetes. Apgar scores were 4 at one minute and 9 at five minutes. The birth weight was 2.41 kg. Increasing tachypnea and tachycardia necessitated transfer to the Winnipeg (Manitoba, Canada) Children's Centre at 3 days of age.

Physical examination showed a coarsely featured, strikingly hirsute infant who, in spite of his emaciated appearance, was vigorous and cried lustily. Figure 1 illustrates the major physical findings. Measurements were: weight, 2.41 kg (< third percentile); length, 49.5 cm (50th percentile); and head circumference, 35 cm (50th percentile). Abundant dark scalp hair had a reddish tinge in the preauricular regions. The ears were large, low set, and lacked complete cartilaginous development. The eyes were normal. The base of the nose was depressed, and the nares anteverted. The mouth appeared large, the lips thick, and the gingiva hypertrophied. The nipples were prominent and the areolae small; there was no palpable breast tissue. Mild tachypnea was associated with moderate intercostal retraction. The pulse was 180 beats per minute, and the systolic blood pressure was 68 mm Hg. There was a prominent right ventricular heave and a grade 3/6 midsystolic ejection murmur maximal at the midsternal borders. The peripheral pulses were normal. The abdomen was protuberant, the abdominal muscular tone was poor, and a small umbilical

Fig 1.—Patient at 4 days of age, with predominant physical features including loose, wrinkled skin, hirsutism, abdominal distention, prominent external genitalia, depressed nasal bridge, anteverted nares, large mouth, thick lips, and gingival hypertrophy.

From the Department of Pediatrics (Drs Rosenberg, Haworth, Degroot, and Trevenen), University of Manitoba, Winnipeg, Manitoba, Canada; and the Laboratory of Biochemical Pharmacology (Dr Rechler), National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health, Bethesda, Md.

Reprint requests to 903 Medical Arts Bldg, 233 Kennedy St, Winnipeg, Manitoba, Canada, R3C 3J5 (Dr Degroot).

hernia was present. There was no abdominal organomegaly. The penile length was normal (3.5 cm), but the genitalia appeared prominent perhaps because of the lack of surrounding subcutaneous tissue. The skin was dry, deeply pigmented, loosely wrinkled, and covered with excessive, fine, dark hair on the face, back, and extensor surfaces of the limbs. There was a lack of subcutaneous tissue and muscle mass. Joint and neurological examinations showed no abnormalities. The infant had a pronounced musty odor.

LABORATORY FINDINGS

Standard Tests

Values for the following studies were normal: hemoglobin, WBCs and platelets, serum electrolytes, indices of acid-base status, sweat chloride concentration, quinacrine-banded karyotype, immunoglobulins, lymphocyte transformation after concanavalin A and *Candida* mitogenic stimulation, and lymphocytic response and stimulator capacity in allogeneic-mixed lymphocyte cultures.

The BUN level ranged from less than 3 mg/dL initially to 14 mg/dL at 35 days of age. The creatinine clearance was 64 mL/min/sq m at 26 days of age. Proteinuria (346 mg/sq m/24 hr) and intermittent glycosuria were present. Intravenous pyelography demonstrated retention of contrast medium within the collecting tubules of otherwise normal kidneys. The serum bilirubin level was 13.8 mg/dL at 4 days of age and was still elevated (4.9 mg/dL) when last evaluated at 5 weeks of age. Direct reacting components of the total bilirubin ranged from 1.5 to 1.8 mg/dL. The SGOT and alkaline phosphatase values were normal. The total serum protein level was 4.6 g/dL. The chest roentgenogram demonstrated a globular-shaped heart and decreased pulmonary vasculature. There was ECG evidence of biventricular hypertrophy and overload. A right-sided heart catheterization, performed at 4 days of age, demonstrated a moderate left-to-right shunt at the atrial level and a slight narrowing of the main pulmonary arteries. The bone age was compatible with a gestational age of 36 weeks.

The urine contained 3% reducing substances and showed positive reactions to 2,4,-dinitrophenylhydrazine (DNPH) and nitrosonaphthol tests, indicative of α-ketoaciduria and tyrosyluria, respectively.[23] Plasma amino acid thin-layer chromatography demonstrated an elevated tyrosine level of .370 μmole/mL (normal, .069 ± .016[24]). Determination of urinary excretion of tyrosyl substances by gas chromatography and mass spectrometry documented elevations of *p*-hydroxyphenylpyruvic, *p*-hydroxyphenyllactic, and *p*-hydroxyphenylacetic acids. At 36 days of age, after five days of ascorbic acid (vitamin C) therapy (100 mg/day), the reactions to the DNPH and nitrosonaphthol tests were negative and the plasma tyrosine level had decreased to 0.029 μmole/mL.

Table 1.—Simultaneous Glucose and Insulin Levels Before and After Feeding

Age, Days	Values Before (After) Feeding	
	Glucose, mg/dL	Insulin, μU/mL
45	92 (181)	1,580 (2,600)
45	13 (219)	660 (ND)*
46	91	2,480

*ND indicates not determined.

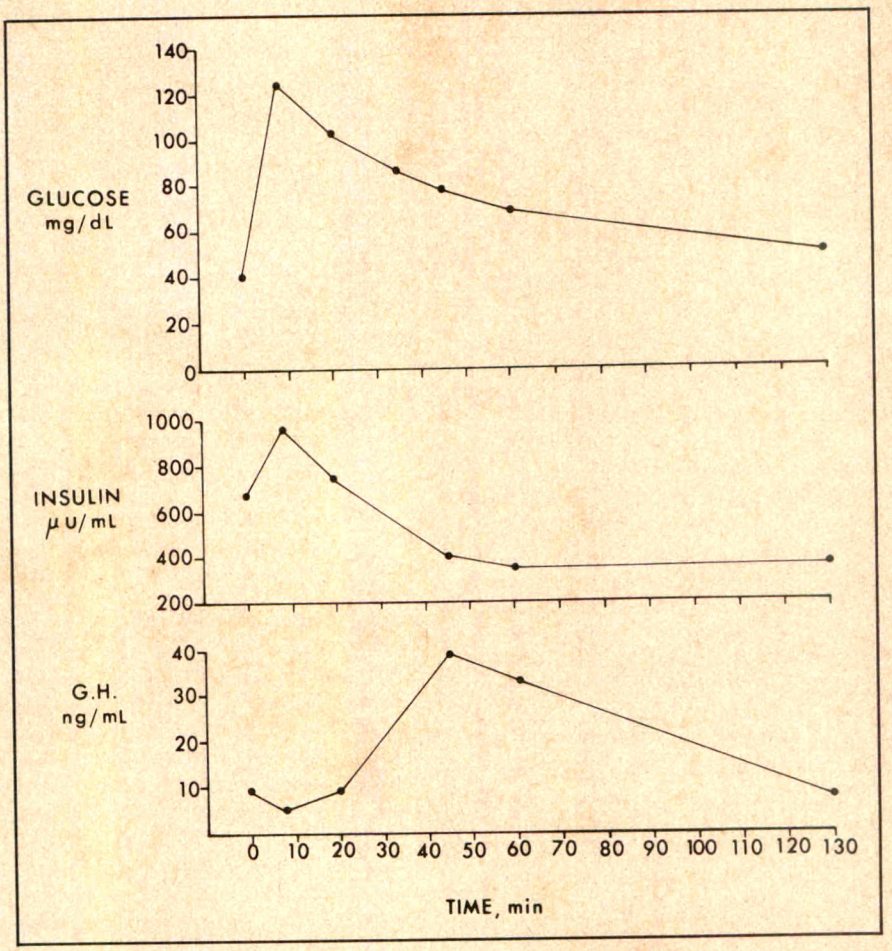

Fig 2.—Plasma glucose, insulin and growth hormone (GH) levels after intravenous injection of 0.5 g/kg of dextrose.

Insulin Resistance

Plasma glucose levels of 43 mg/dL, 133 mg/dL, 90 mg/dL, and 42 mg/dL were obtained during the first 12 days of life. Subsequently, hypoglycemia (plasma glucose ≤ 30 mg/dL) was documented on four occasions with values of 26 mg/dL, 24 mg/dL, 13 mg/dL, and 30 mg/dL at ages 36, 41, 45, and 46 days in spite of oral formula feedings every three hours providing approximately 180 kcal/kg/day. There were no specific clinical signs of hypoglycemia during these episodes. Intravenous

Table 2.—Plasma Values for Patients Mother During Oral Glucose Tolerance Test

Time, hr	Glucose, mg/dL	Insulin, μU/mL
0	89	186
1/2	183	554
1	228	537
2	202	632
3	135	572
4	76	534
5	63	345
6	54	178

and oral dextrose supplementation given during hypoglycemia resulted in rapid stabilization of the plasma glucose level. In all cases, glucose determinations were performed using fresh blood samples obtained from capillary or peripheral venous sites.

Radioimmunoassayed serum insulin levels[25] ranged from 600 to 2,600 μU/mL (normal fasting, 15 μU/mL; normal peak during glucose tolerance testing, 60 to 100 μU/mL). Table 1 lists simultaneous glucose and insulin levels determined immediately before and after feedings. Although insulin levels were consistently elevated when measured at 45 and 46 days of age, the lowest insulin values were obtained when the plasma glucose was correspondingly low, and the highest values were obtained when the plasma glucose level was normal or high.

An intravenous (IV) glucose tolerance test (GTT) was performed at 17 days of age after a six-hour fast. Plasma glucose and immunoreactive insulin[25] and growth hormone[26] levels after IV dextrose administration (0.5 g/kg) are shown in Fig 2. The results indicate normal glucose and growth hormone levels despite sustained hyperinsulinemia. In spite of a borderline low fasting blood glucose level of 40 mg/dL, the corresponding insulin level was high (660 μU/mL). As the blood glucose increased to 125 mg/dL, there was an additional increase in insulin to 960 μU/mL. The rate of glucose disappearance (K_t)[27(p31)] was 1.41%/min. (A normal K_t value from an appropriate control group matched for age, nutritional status, duration of pretest fasting and dose of dextrose is not available. Cornblath et al cited K_t values of 1.65 to 3.50 %/min in infants and children[27(356-367)] and reported a K_t of 0.87 ± 0.11 %/min in low-birth-weight infants less than 3 days of age but significantly higher values in older neonates.[28])

Gel filtration and insulin radioimmunoassay (RIA) of the patient's serum were performed. A 0.5-mL sample of the patient's serum was fractionated on a 50 × 1-cm column (Sephadex G-50) using markers of insulin I 125 and proinsulin I 125.[29] Fractions were assayed by insulin RIA using rabbit antiguinea pig second antibody.[30] The proinsulin peak contained 13% of the immunoreactivity, and the insulin peak 87% of the immunoreactivity, a normal distribution. The void volume showed no apparent immunoreactivity, thereby excluding anti-insulin antibodies. (If anti-insulin antibodies were present, they would bind insulin I 125 but not be precipitated by rabbit antiguinea pig second antibodies since they are human antibodies.) The insulin peak was lyophilized, reconstituted, and assayed in the glucose oxidation bioassay in isolated rat adipocytes.[31] The biological activity (relative to porcine insulin standard) was 70% of the immunoreactivity (on the chromatographed, lyophilized, resuspended sample).

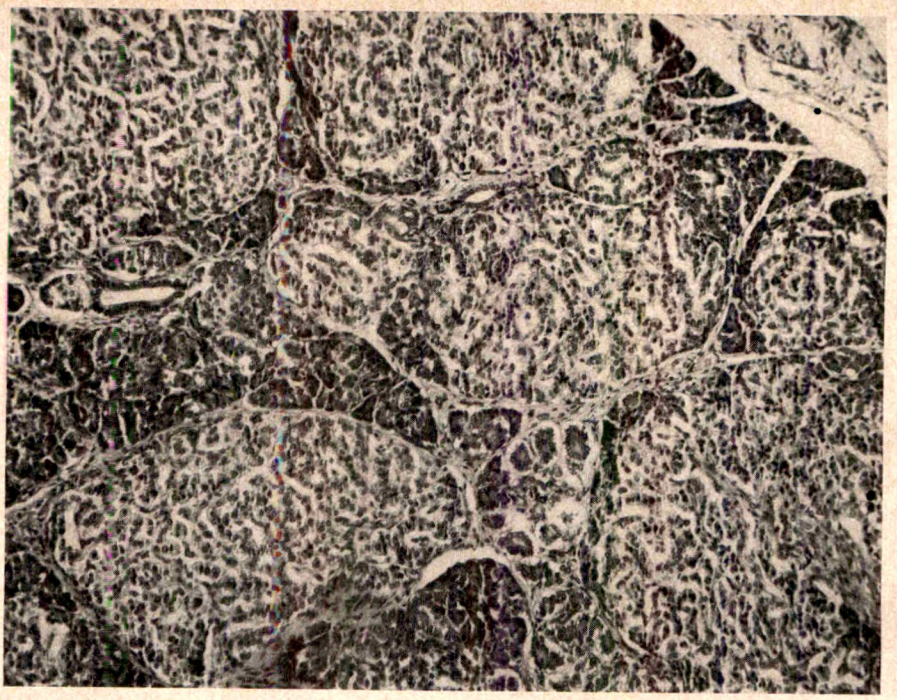

Fig 3.—Pancreas showing striking hyperplasia of islets (hematoxylin-eosin, original magnification ×120).

Table 2 documents the glucose and corresponding insulin levels of this patient's mother, obtained during a six-hour oral GTT that was performed eight months after her son's birth. The values indicate that she also had normal or high plasma glucose levels in the presence of sustained hyperinsulinemia. As her plasma glucose level increased to more than 200 mg/dL, there was an increase of plasma insulin from the fasting level of 186 μU/mL to a maximum of 632 μU/mL at two hours. Since the mother was mildly obese, her obesity may have been a factor contributing to the noted abnormalities of her GTT.

COURSE IN HOSPITAL

The patient fed well but weight gain was poor, and he remained frail and emaciated. Periods of increasing respiratory distress developed in association with intermittent, unexplained abdominal distention. Pneumonia developed at 34 days of age and resolved rapidly with antibiotic therapy; an etiological agent was not isolated. The infant died shortly after the start of diazoxide therapy (10 mg/kg/day), and its effectiveness in controlling glucose homeostasis could not be evaluated.

Death occurred suddenly at 47 days of age and was unassociated with fasting, recent feeding, or any appreciable change in the patient's clinical status in the immediate premortem period.

POSTMORTEM FINDINGS

Notable findings included cardiomegaly (45 g; normal, 26 g) with biventricular hypertrophy, a small (0.2-cm diameter) patent ductus arteriosus, small lymph nodes and thymus, a small firm bile-stained liver, and bilaterally enlarged kidneys with prominent yellow streaks in the renal papillae. There was severe gaseous distention of both small and large bowel and mild dilation of the ureters above the pelvic rim.

Microscopically, the most striking feature was hyperplasia of the pancreatic islets (Fig 3). The islets were increased both in number and in size, and aldehyde fuchsin stains as well as ultrastructural examination confirmed the predominance of β cells. The liver showed dilation of the collecting tubules, most of which contained granular, basophilic casts. Pituitary, thyroid, parathyroids, and testes showed no abnormalities on light microscopy whereas adrenal cortical cells showed moderate lipid depletion. Lymph nodes, though small, had good primary and secondary fol-

licular development, and the thymus showed only stress involution.

COMMENT

We know of detailed reports of 24 cases of leprechaunism originating from four continents and including many racial groups. Table 3 summarizes the predominant historical and physical features of previously reported cases and includes the present patient. Table 4 summarizes the histopathological findings of those patients who have had biopsies or postmortem examinations.

Clinical and Laboratory Features of Leprechaunism

Most of the previously reported patients share many distinguishing physical features, but there are others who are less typical[3,4] and in whom the diagnosis of leprechaunism has been questioned.[6,32] Dallaire et al[32] described three infants with an apparently distinct syndrome of generalized elastic fiber deficiency and leprechaunoid features. Two patients included in the present review also had histopathological confirmation of elastic fiber deficiency[4,18] and may represent additional cases of the syndrome described by Dallaire et al.

A high frequency of parental consanguinity[2,5,12,18,19,22] and familial occurrence[2,12,16,17,22] suggest that leprechaunism is transmitted by an autosomal recessive mode of inheritance. The presence of hyperinsulinemia in our patient's mother further suggests that genetic factors may be important in the etiology of leprechaunism although the mother's mild obesity may have been a factor contributing to her hyperinsulinemia. It is hoped that detailed studies of our patient's family can be undertaken to provide further insight into possible patterns of inheritance. Apart from 46XY Cp+[9] and 46XXGq+[16] karyotypes, chromosomal studies have been normal in the nine cases studied. In their discussion of a 17-month-old female infant, Hopwood and Powell[33] suggested that leprechaunoid features may be manifestations of emotional deprivation; however, this could not be considered an etiological factor in patients with features of leprechaunism present at birth.

The pathophysiology of leprechaunism has not been satisfactorily defined. As was our experience, the comprehensive evaluation of possible pathogenic mechanisms frequently has been limited by the patients' precarious conditions or early deaths.

As in the present case, proteinuria,[1,3,8,14,22] glycosuria,[1,16,21,22] and aminoaciduria[4,5,11,13] have been noted. Elevation of the BUN was reported in four patients,[3,14,18,19] one of whom had an associated increase in serum creatinine.[14] Substantial anatomical renal abnormalities have not been reported. In four cases, including our patient, hyperbilirubinemia was present.[17,20,22] In the two patients in whom the serum thyroxine level was low, the serum triiodothyronine and protein-bound iodine (PBI) levels were normal in one,[15] and the T_3 resin uptake showed increased levels in the other[22]; in four other patients, the PBI value was normal.[4,6,13,14]

By using differential staining techniques, Rogers[8] suggested that the pituitary basophilic predominance noted in three patients represented gonadotrophin-secreting basophils. This suggestion would be consistent with the gonadal enlargement noted in some cases but is inconsistent with the few reports of normal assays of luteinizing and follicle-stimulating hormones.[3,4,6,12,14,22] Autopsy findings frequently have demonstrated small adrenal glands, but in at least two patients, the zona fasciculata was prominent. In the two patients in whom plasma cortisol levels were reported, one had increased levels[14] and the other had normal values.[22] Urinary excretion of 17-hydroxycorticosteroids were normal in a number of other patients.[4,5,11-14,16,17]

Intercurrent infections were fre-

quently noted and included cutaneous abscesses,[1,2,6,7,17] pneumonia,[1,2,5,7,14,18,19] meningitis,[8] and gastroenteritis.[14] Consistent with the findings in our patient, previous reports have reported normal immunoglobulin levels[12,14] and normal T-cell function.[14] Delayed bone age has been a frequent radiological sign, including the present case.[3-6,8,11-13,16,17,20] Nonspecific EEG abnormalities[12,14] and right cortical atrophy on pneumoencephalography[3,14] have been demonstrated.

Carbohydrate Metabolism and Insulin Resistance in Leprechaunism

Of the 20 patients in whom carbohydrate metabolism was evaluated, 18 (90%) were considered by the respective authors to have had biochemical evidence of abnormal glucose homeostasis, including our patient.* Hypoglycemia was reported in seven patients (including the present case)[3,5,6,15,18,19] but was often based on only a single low glucose value. In one case, depletion of glycogen stores as a cause of hypoglycemia is suggested by a negligible increase in blood glucose after adrenalin and glucagon stimulation.[6] Glucose tolerance tests were interpreted as abnormal in seven patients.[5,11,12,14,16,17,21] Excessive elevations of the blood glucose levels were noted during GTTs for three patients,[11,17,21] and in four others, the GTT curves were considered flat.[5,12,14,16] Of the eight patients for whom insulin tolerance tests were performed, two had normal values,[14,16] five demonstrated excessive and prolonged hypoglycemia,[3-6] and one showed a blunted hypoglycemic response.[21]

Elevated blood insulin levels were reported in four patients (including the present case)[18,21,22] and were normal in two others.[9,16] In discussing their patient, Summitt and Favara[11] interpreted as normal a plasma insulin level of 35 mμg/mL (840 μU/mL), but this value seems high. In addition to the present case, one other patient had hyperinsulinemia associated with pancreatic islet cell hyperplasia.[22]

Pancreatic islet cell hyperplasia was noted in eight other cases at autopsy, suggesting that they also may have had hyperinsulinemia. However, a sibling of the patient described in detail by Tsujino and Yoshinaga[17] was reported to have had leprechaunoid features, normal insulin levels, and pancreatic islet cell hyperplasia, indicating that pancreatic hyperplasia may not necessarily reflect hypersecretion of insulin.

Despite the extraordinarily high plasma insulin levels in our patient, hypoglycemia was intermittent, generally mild, and easily corrected by dextrose supplementation. As illustrated in Fig 2, the blood glucose levels were relatively well maintained even in the presence of sustained hyperinsulinemia. The apparent inconsistency between the plasma glucose levels and the severe hyperinsulinemia suggested some degree of insulin resistance. In vivo insulin tolerance testing was not performed for our patient. However, in vitro studies demonstrated that the patient's insulin was normal in size and biological activity. His plasma contained no antibodies to insulin nor to insulin receptors (R. Chochinov, MD, oral communication, June 28, 1978). The binding of insulin I 125 to cultured fibroblasts from this patient and from controls was studied. A profound and selective deficiency of insulin binding to the patients' fibroblasts was observed, indicating a primary defect of insulin receptors.[34] A detailed account of the methodology and results of the insulin binding studies in our patient is described in a separate report.[34]

Jacobs et al[35] and Hill[36] have described an infant with leprechaunoid features, hyperinsulinemia, and a profound decrease in insulin binding to circulating erythrocytes. Whether this insulin receptor defect is genetic (primary) or acquired (secondary) must await the results of fibroblast binding studies.

Kobayashi et al,[21] in their study of a two-year-old girl with leprechaunoid features and marked hyperinsulinemia presented evidence suggesting that their patient's insulin resistance might be due to a cellular defect in the coupling mechanism between insulin receptors and the plasma membrane

*References 3-6, 11, 12, 14-19, 21, 22.

glucose transport system. In their patient, circulating insulin was qualitatively normal, anti-insulin receptor and anti-insulin antibodies were absent, and insulin binding to circulating monocytes was normal.

D'Ercole et al[22] reported insulin resistance in an infant with leprechaunoid features. The insulin of their patient demonstrated chemical and biological characteristics of normal insulin, and insulin I 125 bound normally to cultured fibroblasts. The defect in this patient remains undefined but does not seem to involve a primary abnormality of insulin receptors.

Similarities of physical features between patients reported to have leprechaunism and those with insulin resistance associated with other disorders[37-40] suggest that leprechaunism may not be a distinct clinical entity but may be allied, both clinically and pathophysiologically, with other morphologically similar conditions. For example, patients with leprechaunism have certain similarities to patients with congenital lipodystrophy (lack of subcutaneous fat, insulin resistance) although the patients with lipodystrophy typically exhibit normal or increased growth and well-developed musculature.[37-40]

The group of patients with leprechaunism seems to be heterogeneous with respect to the clinical manifestations exhibited by individual patients and with respect to both the occurrence of insulin resistance and its molecular basis. The exaggerated decrease of blood glucose in response to insulin administration observed in some patients and the normal insulin levels in others suggest that insulin resistance may not be an operative mechanism in all patients with leprechaunoid features. Even among patients with leprechaunism and insulin resistance, however, our patient seems to be unique in having a genetic abnormality of his insulin receptors as a presumed basis for insulin resistance.

Alisdair Hunter, MD, rendered valuable contributions to the patient's care and gave his support during the preparation of this manuscript. Carl Grunfeld, MD, PhD, and Ellen Schilling provided advice and technical assistance.

Gel filtration and insulin radio immunoassay (RIA) were performed by Philip Gorden, MD, Carla Hendricks, and Janice Ryan, Diabetes Branch, National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health. Glucose oxidation bioassay was performed by Kathleen Baird, also of the Diabetes Branch.

Diane Thompson, RN, and the pediatric housestaff, Winnipeg (Manitoba, Canada) Children's Centre extended their cooperation.

Fever Phobia

Misconceptions of Parents About Fevers

Barton D. Schmitt, MD

• Eighty-one parents bringing their children to a hospital-based pediatric clinic were surveyed about their understanding of fever. Most parents were unduly worried about low-grade fever, with temperatures of 38.9 °C or less. Their overconcern was designated "fever phobia." Most parents (52%) believed that moderate fever with a temperature of 40 °C or less can cause serious neurological side-effects. Hence, most parents treated fever aggressively: 85% gave antipyretic medication before the temperature reached 38.9 °C and 68% sponged the child before the temperature reached 39.5 °C. A review of the literature showed that the only serious complications of fever were febrile status epilepticus and heat stroke, two rare entities. The great concern of parents about fever is not justified. Health education to counteract "fever phobia" should be a part of routine pediatric care.

(*Am J Dis Child* 134:176-181, 1980)

A controversy in medical theory and practice since ancient times has been the question of whether a physician ought to fight fever, ignore it, or encourage it. For ancient humoral pathologists, fever was the most important of the body's natural defenses when the amount of "phlegm" in the body increased. The doctrine stated that the heat of fever was designed to drive the excess phlegm out of the body. Fevers were encouraged and celebrated. By the middle of the 19th century, Claude Bernard had completed his experiments on the overheating of animals and had proven that death quickly occurred if the body's temperature rose 5 to 6 °C above normal.[1] Thereafter, fever gradually was looked on as injurious to health, and treatment with antipyretic medication was considered essential.

Although modern physicians have achieved a more balanced perspective on the treatment of fever, many parents seem to be as fearful of fever as physicians were a century ago. The purpose of this study was to determine the prevalence of parental misconceptions about the dangers of fever and the home treatment of fever. The literature was reviewed in an attempt to delineate the level of fever that is harmful and what the harmful effects are.

SUBJECTS AND METHODS

One hundred parents bringing their children to a university-based walk-in clinic were asked to complete a one-page questionnaire on their understanding of fever while waiting to see a physician. Many of the children were not acutely ill at the time of the visit. Eighty-one parents completed the questionnaire and returned it to a member of the clinic staff. The parents were given no assistance with answering the questions, but on completion of the questionnaire, the clinic nurse reviewed the appropriate answers with the parents as time permitted. Fifty-seven percent of all the families surveyed had one child, 32% had two, 12% had three, and 9% had four or more.

Of note is the fact that 14% of all the families had an only child younger than 6 months of age and hence their past experience with febrile illnesses may have been limited. Generally speaking, 50% of all the families seen in this clinic are medically indigent, 40% are part pay, and 10% pay the full fee. The questions asked in the questionnaire were as follows. (1) What do you consider a "high" fever? (2) If your child had a fever and you didn't treat it with aspirin or acetaminophen (Tylenol), how high could it go? (3) In your opinion, what is the greatest harm that *high* fever can cause to a child? (4) How *low* a temperature can cause the types of harm you listed in question 3? (5) How worried are you about what fevers can do? (6) If your child has fever, how often do you continue to take his temperature? (7) Above what temperature do you give aspirin or acetaminophen? (8) How often do you give aspirin or acetaminophen for fever? (9) If your child has fever when you put him down for the night, do you awaken him or her during the night to

give acetaminophen or aspirin? (10) Above what temperature would you sponge your child? (11) How did you learn your ideas about fever: from what your doctor or nurse does when you bring your child in with fever; from what physicians and nurses have told you; from friends and relatives; from reading.

RESULTS

Figures given in Table 1 shows that 58% of all parents consider fevers of 38.9 °C (102 °F) or less to be "high fevers." Those given in Table 2 show that 16% of all parents think an untreated fever can keep rising to 43.3 °C (110 °F) or higher. Anyone holding this misconception would probably fight fever as if their child's life depended on it.

Results given in Table 3 remind us that 94% of all parents believe fever can cause side-effects, and 62% believe it can cause permanent harm, the most common concern being "brain damage." Table 4 contains the parents' definitions of a "dangerous fever," the level of fever that can cause the harmful effects listed in Table 3. Surprisingly, 52% of all parents believe that these serious and rare complications can occur with fevers of 40 °C (104 °F) or less, and 18% believe these can be caused by fevers of 38.9 °C (102 °F) or less.

The responses to question 5 show that 63% of all parents "worry lots" about possible harmful effects from fever, 36% "worry some," and only 1% did not worry. The responses to question 6 demonstrate that 8% of all parents take, or think they should take, their child's temperature every hour if the child is febrile. This behavior probably points to a concern that the temperature may rise quickly. Thirty-five percent of all parents took the temperature five to eight times per day.

Table 5 demonstrates that 56% of all parents give antipyretic medications for temperature of 37.0 to 37.8 °C (ie, possibly normal temperatures). A total of 85% give antipyretic medications before the temperature reaches 38.9 °C (102 °F). The responses to question 8 confirm that most parents know the correct interval for giving antipyretic medication, but that 7% may give it inadequately (one to two times per day) and 4% may inadvertently overdose their child (by giving it every one to two hours).

Table 1.—Parent's Definition of a 'High Fever'

°C	°F	% of Parents
37.8	100	12
38.4	101	11
38.9	102	35
39.5	103	32
40.0	104	8
40.6	105	2

Table 2.—Parent's Understanding of How High a Fever Can Go If They Do Not Treat It

°C	°F	% of Parents
40.6	105	52
41.7	107	32
43.3	110	9
45.0	113	2
46.1	115	1
48.9	120	4

Table 4.—Parent's Definition of Lowest Temperatures That Can Cause Type of Harm Listed in Table 3

°C	°F	% of Parents
37.8	100	4
38.4	101	7
38.9	102	7
39.5	103	8
40.0	104	26
40.6	105	27
41.1	106	6
41.7	107	6
42.2	108	3
43.3	110	6

Table 5.—Temperatures Above Which Parents Would Give Antipyretic Medications

°C	°F	% of Parents
37.0	98.6	11
37.8	100	45
38.4	101	29
38.9	102	8
39.5	103 or higher	7

Table 6.—Temperatures Above Which Parents Would Initiate Sponging

°C	°F	% of Parents
37.8	100	7
38.4	101	14
38.9	102	42
39.5	103	30
40.0	104	6
41.1	106	1

The responses to question 9 showed that 48% of all parents are so worried about fever that they would awaken their child to give additional medication. Table 6 shows that 20% of all parents would sponge their child if the temperature reached 37.8 to 38.4 °C (100 to 101 °F), and an additional 42% would sponge if it reached 38.9 °C (102 °F).

Table 7 reminds us that health personnel are important teachers of parents concerning fevers. Some 51% of all parents credit physicians and nurses with being their main source of information. This group of parents and the two groups that stated they learn about fevers from other sources were compared in terms of how often they gave inappropriate responses to the previous nine questions. No significant differences were found on the χ^2 tests. There was a suggestion, however, that the group who relied on reading more frequently gave appropriate answers.

Table 7.—Parent's Source of Information About Fevers

Source of Information	% of Parents
What doctors or nurses said	34
What doctors or nurses did	17
Friends or relatives	30
Reading	19

Overall, the answers to questions 1, 2, and 5 suggest that many parents are unduly worried about fevers. Tables 3 and 4 suggest that most parents worry about serious permanent damage from fevers. It is therefore not surprising that most parents treat fevers overaggressively, as seen by the responses to questions 7, 9, and 10.

COMMENT

The evidence clearly shows that many parents are greatly concerned about fevers in their children. In fact, some worry about a universal phenomenon, the low-grade acute fever that every child experiences repeatedly. Because this fear is unrealistic, this condition has been designated "fever phobia." The literature was reviewed on three related topics: the maximal levels of fever reported in children with acute infectious diseases, the level of fever that can cause harm, and what those harmful effects are. There are also some suggestions for counteracting fever phobia.

The Highest Level of Fever in Children With Infectious Diseases

Hyperpyrexia is generally defined as a temperature of 41.0 °C or greater. Fevers of this magnitude are rare. Tomlinson's study[2] on high fevers in ambulatory patients during 13 years of private pediatric practice reported temperatures of 40.0 to 40.5 °C in 78 children, 40.5 to 41.0 °C in 28 children, and higher than 41.1 °C in two children. In a large pediatric emergency room, McCarthy and Dolan[3] found 100 children with temperatures of 41 °C or greater over an eight-year span. The incidence was one child with hyperpyrexia for 2,100 patient visits.

Studies of inpatients have found a higher incidence of hyperpyrexia. Akerren[1] reviewed inpatient records for the highest recorded temperature and found that 1.5% of all children have a temperature reading of 41.0 °C or greater. DuBois[4] examined the charts of 357 adult patients with diseases noted for high fever, namely pneumonia, relapsing fever, malaria, and induced malaria. These patients had 1,761 temperature readings recorded, and of these readings 4.3% were above 41.1 °C and none were above 42 °C. DuBois concluded that "an emergency regulatory mechanism exists that sharply limits the temperature at the level of about 41.1 °C (106 °F)."

If common infectious diseases are an unusual cause of hyperpyrexia, what are the usual causes of temperatures greater than 41.1 °C (106 °F)? Between 41.1 and 41.7 °C (106 and 107 °F), infections of the CNS play an important role, presumably due to the direct effect of the infection on the hypothalamus. In McCarthy and Dolan's study,[3] 10% of all the children with hyperpyrexia had bacterial meningitis and 3% had aseptic meningitis. In Akerren's study,[1] 15% of all the children with hyperpyrexia had acute CNS disease (mainly meningitis) and 33% had underlying chronic brain defects, such as trisomy 21, hydrocephalus, brain tumor, and mental retardation. In DuBois' study,[4] the highest temperatures were recorded in patients with malaria, and one can speculate that some of the patients had cerebral malaria. Most temperatures above 41.7 °C in children without CNS disease are due to human error from excessive heat load or from interference with heat loss. Examples are wrapping a febrile child in too much clothing or blankets, covering a child with burns or eczema in too many dressings, placing a baby near a radiator, placing a child in a car in direct sunlight, or placing a child in a homemade steam tent.[5] All of these errors are more dangerous during a heat wave. One study on hyperpyrexia found that 64% of all the cases occurred between June and September, supporting the view that ambient temperature may be a factor.[6] Rarely, a child develops hyperpyrexia because of physical exertion while receiving a medication that prevents sweating (eg, phenothiazine or atropine).[7]

The Harmful Level of Fever

Discomfort with fever usually does not begin until the temperature reaches 39.5 or 40.0 °C (103 or 104 °F). Every physician has seen children who are happy and playful and who to everyone's surprise are found to have a temperature of this level. DuBois[4] reported temperatures to 40.0 °C that occurred after hard exercise. Newburgh[8] reported temperatures of 41.0 °C (105.8 °F) in persons at the end of a three-mile race. Obviously, acute fevers of this level cannot be considered dangerous. In their treatment of neurosyphilis, fever therapists produced and maintained fevers of 42 °C (107.6 °F) in patients for eight to ten consecutive hours by using a hyperthermia cabinet set at 54.4 °C (130 °F).[9] Although many of the patients experienced disorientation and vomiting, heat stroke was uncommon and the mortality was less than 0.5% when appropriate means were used to correct dehydration and hypoxia.[9] Artifically induced fevers of 41.5 to 42.0 °C for several hours are currently being used in some centers to treat metastatic tumors.[10,11] Sharp regression of the tumor is seen in some patients.

The literature was reviewed for statements on dangerous or harmful levels of fever. The information obtained is given in Table 8. Most of the warnings relate to a breakdown of the heat regulatory mechanisms (ie, heat stroke). Few data could be found on the relationship of body temperature to cellular death of normal cells. Recent studies have shown that tumor cells are more thermal sensitive than are normal cells.[10] Only three authors mention studies or case reports.[1,4,8] Relevant comments were found in one pathology textbook,[12] three physiology textbooks,[13-15] and three pediatrics textbooks.[16-18] Although the data leave much to be desired, the consensus seems to be that temperatures under 41 °C are relatively harmless, that most people can tolerate temperatures of between 41 and 42 °C without a heat stroke developing and temperatures over 42 °C are usually harmful.

The Harmful Effects of Fever

Fever rarely causes any permanent harm. Dehydration can occur due to increased fluid loss with sweating, but this is preventable with attention to the child's thirst and fluid needs. Delirium or toxic encephalopathy can be caused by febrile illnesses as well as other nonfebrile disorders.[19] Delirium is more an inconvenience than a threat to the child's well-being. Since more than 50% of all children with meningitis have associated delirium, this diagnosis should always be considered in delirious children.[20] The two complications of fever that can lead to permanent bodily harm are febrile status epilepticus and heat stroke.

Heat stroke can be defined as a catastrophic condition characterized

Table 8.—Definitions of Harmful or Dangerous Temperatures From the Literature

Source	Definition of Harmful Temperature, °C (°F)	Comments by Author
Dubois[4]	41	Harmful
	42	Dangerous if prolonged
Akerren[1]	42	Fatal outcome rapidly occurs
Newburgh[8]	43	Upper limit of human temperature, few survivors above this
Florey[12]	41.1 (106)	Heat regulating mechanism starts to fail
	43.3	Coma
Ganong[13]	41.1 (106)	Some brain damage if prolonged
	43	Death is common
Guyton[14]	41.7 (107)	Heat regulating mechanism starts to fail
	43.3 (110)	Death in a few hours
Vander et al[15]	41.1 (106)	Harmful
	41.7 (107)	Convulsions
	43.3 (110)	Death
Frothingham[16]	41	Heat stroke may occur
Pascoe and Grossman[17]	41.1 (106)	High fever, but not an emergency
Ryan[18]	41.1 (106)	Possibly dangerous*

*This author, however, has described nine patients with temperatures above 108 °F who did not have sequelae.

by hyperpyrexia (usually over 42.0 °C), delirium, coma, and anhidrosis.[21] Heat stroke appears to result from a breakdown in the hypothalamic heat regulatory mechanism. Without treatment, the mortality can be as high as 80% and the survivors can have neurological deficits, including cerebellar ataxia and severe dysarthria.[21] Of note, during a Cincinnati heat wave, every patient with heat stroke whose temperature on admission to the hospital was less than 41.7 °C survived.[22] The incidence of neurological sequelae was not recorded. Heat stroke should rarely occur with the usual childhood febrile illnesses unless the child is excessively clothed, the site of infection is the CNS, or the child has an underlying disease that limits sweat production (eg, anhydrotic ectodermal dysplasia).

A febrile seizure is the best-known complication of a high fever, and such seizures occur in 4% of all children with high fever.[23] Whether or not simple febrile seizures per se lead to permanent neurological sequelae is controversial. The incidence of afebrile seizures in children who have experienced febrile seizures is 2%, which is greater than the incidence of seizures in the general population.[24] It is doubtful that children with febrile seizures have an increased incidence of mental retardation or learning disorders.[25]

Febrile status epilepticus can be defined as a febrile seizure lasting longer than 60 minutes.[26] Seizures of this duration occur in 1%[27] or 2%[23] of all children with febrile seizures. These prolonged febrile seizures can cause severe brain damage. The damage is probably due to hypoxia associated with the seizure or to aspiration and airway obstruction.[23,28] Millichap[23] found evidence of subsequent brain damage in less than 0.2% of all children with febrile seizures. These figures suggest that status epilepticus can occur without subsequent brain damage.

The physician should attempt to prevent febrile status epilepticus. The only treatment regimen proven to be effective in preventing the recurrence of febrile seizures is administration of continuous prophylactic phenobarbital.[27,29] Once a seizure begins, it should be treated vigorously to prevent any progression into status epilepticus. Bringing the temperature below the seizure threshold for that child is probably the most practical approach.[23]

One question that remains unanswered is whether or not the first febrile seizure could be prevented by vigorous early treatment of all suspected infections with antipyretics. No study has yet proved that vigorous treatment with antipyretics is effective in decreasing the number of febrile seizures. Two pieces of information make this notion doubtful. At the time of onset of febrile seizures, 30% of all parents are unaware of the presence of a fever, in 61% of all cases the fever has been present less than 12 hours, and in 81% of all cases the fever has been present less than 24 hours.[27] In addition, febrile convulsions can occur in the face of moderate temperature elevations. Wolf et al[27] found that 81% of all seizures occurred at 40.0 °C or less, and Millichap[30] found that 50% of all cases of febrile convulsion occurred at 40.0 °C or less, with a range of 38.5 to 41.4 °C. Therefore, it seems likely that a febrile seizure can occur despite the utmost vigilance and the use of antipyretics.

Guidelines for Counteracting Fever Phobia

Fever phobia is an unnecessary burden for parents. Physicians and nurses who provide medical care for children can help parents gain a better perspective on fever. Fever can be discussed at the fourth- or sixth-month health supervision visit in anticipation of the inevitable febrile illnesses to come. We can emphasize that fevers do not automatically require therapy.[31] We can stress with parents that the harmful effects of fever are rare. We can underscore the fact that fever is the body's normal response to infection and may even have some beneficial effects. Indeed, fever has been shown to limit the replication of some common viruses.[32] The following ten guidelines may prove helpful for counseling parents.

(1) Define fever as a temperature over 37.8 °C (100 °F) orally or 38.0 °C (100.5 °F) rectally. On a warm day, a child who has a temperature of between 38.0 and 38.5 °C should have his temperature taken again after he has had a half hour to cool off, before making a diagnosis of fever. We can define a high fever as a temperature

higher than 40.5 °C (105 °F) and mention that harm from fever does not begin until the temperature is 41.1 or 41.7 °C (106 or 107 °F).

(2) Use the term "fever therapy" rather than "fever control." Fever control may imply that the fever will go out of control if the parent does not do something about it quickly. Physicians can remind parents that the body has a thermostat for the purpose of controlling fever and this thermostat generally keeps the body temperature below 41.1 °C (106 °F). We can remind parents that the temperature will not climb upward relentlessly.

(3) Recommend treating the child's condition with antipyretic medications only if the temperature is over 39 °C (102 °F) and, preferably, only if the child is uncomfortable. If the child is hospitalized, any standing order that is written for fever medication should also specify the level of fever to be treated. Mention to the parents that low-grade fevers do not require any antipyretic treatment except light clothing and additional fluids. Also, mention that the main reason for treating fever is to help the child feel comfortable, not to prevent harm to the child. In my experience, many physicians who intellectually agree with these indications for medication still tend to prescribe antipyretics for any patient with fever they are consulted about by telephone.

(4) Recommend sponging the child with water (37 °C) only if the temperature is higher than 40 °C (104 °F), has not responded to treatment with antipyretics, and the patient is uncomfortable. The antipyretic must be given one hour before sponging so the hypothalmic set point will be lowered. If sponging is administered before the antipyretic is given, the child experiences discomfort and shivering because the hypothalamus attempts to offset the lowering of the body temperature, and the temperaure quickly returns to the previous level after the sponging is discontinued.[33]

Thirteen current pediatrics textbooks were searched for guidelines about the use of antipyretic medications and/or sponging. Six textbooks had no section on fevers.[34-39] Two textbooks had sections on fever, but no specific recommendations.[40,41] The five textbooks with specific guidelines recommended giving antipyretics for temperatures over 39.0 or 39.5 °C and sponging for temperatures over 39.5 to 40 °C.[16-18,42,43]

(5) Assume a calm approach to fevers. Physicians and nurses serve as models for parents' later behavior around illness. In our offices and clinics, we should not respond to fever as if it were a crisis. We should avoid rapid sponging or keeping the child in the clinic until we bring the temperature below some magic number such as 38 °C. Obvious exceptions to these statements include the child with a temperature over 41.0 °C or who has a febrile seizure. Physicians who obtain routine temperatures on all children who come to the office may also be overemphasizing the importance of undetected fevers in the minds of the parents.

(6) Suggest that the parents not give alternating dosages of acetaminophen and aspirin every two hours. This aggressive approach may suggest to the parents that fever is a grave situation. There is no reported study of the two-hour alternate aspirin-acetaminophen treatment regimen. Only one pediatrics textbook mentions it.[16] One study, comparing a combination of aspirin and acetaminophen to each drug used alone, showed a prolonged six-hour effect from the combination.[44] The combination might be appropriate for a child who has fever at bedtime. One risk of using alternate drugs at two-hour intervals is that if the parents run out of the acetaminophen, they may switch to giving aspirin every two hours and thus cause salicylism.

(7) Suggest that parents not awaken the child from sleep for temperature-taking or administration of antipyretics. Remind them that sleep is valuable for a sick child.

(8) The temperature should be taken before every dose of antipyretic medication to make certain the child does not receive unnecessary medications. On a practical level, very few parents are willing to carry out this instruction. A more reasonable recommendation is to ask parents to repeat giving the medication without taking the temperature if the child is uncomfortable, but to retake the temperature if they are uncertain whether the child still has a fever. The parents should also retake the temperature if the patient is uncomfortable despite treatment and seems extremely hot. This measure would help to recognize any child who has a temperature over 41.0 °C.

(9) Provide special recommendations for the child who has experienced a febrile seizure. The parents of these children want to be involved in a vigorous antipyretic program, whether it is helpful or not. These children can be treated with antipyretic medications at the first sign of fever. This medication should probably be given every four hours for a minimum of 24 hours, since 81% of all febrile seizures will occur in this time span.[27] Awakening the child once during the night to give an antipyretic drug might be a reasonable thing to do, and sponging is an important part of the home first aid for any febrile seizure.

(10) Teach parents that observation of their child's symptoms and signs is more important than the temperature. Emphasize that temperature-taking can never substitute for these more important observations. Parents can be reminded that the main reason for consulting a physician about fever is the presence of worrisome symptoms, such as difficulty with breathing, dysuria, delirium, whimpering, irritability, or pain. The physician usually does not need to be consulted for fever alone, unless it is high (40.6 °C [105 °F] or above), the child is younger than 3 months of age with any fever, the fever persists longer than 24 hours without an obvious site of infection, if the fever persists over 72 hours in any illness, or if the child has a serious underlying disease.

Brian A. Lauer, MD, gave a critical appraisal of this manuscript.

Neurofibromatosis With Congenital Glaucoma and Buphthalmos in a Newborn

Leon Satran, MD; Robert D. Letson, MD; Edward L. Seljeskog, MD

• **A newborn infant with unilateral eyelid swelling, proptosis, and glaucoma is described. The diagnosis of congenital neurofibromatosis was made on the basis of a positive family history and by inspection of the patient. It is suggested that this clinical problem is more common at birth than generally recognized. Clinicians should be aware that congenital glaucoma secondary to neurofibromatosis is a distinct entity that can manifest itself in the newborn period.**

(*Am J Dis Child* 134:182-183, 1980)

Neurofibromatosis is a well-recognized problem in infancy and childhood and exhibits great variability in its clinical manifestations.[1,2] Reports of congenital glaucoma in newborns secondary to neurofibromatosis are extremely rare[3,4] and, to our knowledge, have not been presented in the American literature. This case is being described in an attempt to raise the level of awareness of this condition among clinicians.

Report of a Case

A 3-week-old female infant was admitted to the University of Minnesota Hospitals, Minneapolis, with a history of swelling of the right eye and upper lid since birth. She was born weighing 2,650 g to a primigravida after an uncomplicated 39-week pregnancy. While in the nursery, haziness of the right cornea and swelling of the right upper eyelid were noted. two weeks later, she was seen by a physician who diagnosed her problem as glaucoma and treatment was begun with 1% pilocarpine hydrochloride solution.

The patient's mother and aunt, who are twins, have neurofibromatosis; the mother also has cafe-au-lait spots, scoliosis, and multiple subcutaneous tumors. Examination of the infant showed a maculopapular rash over the scalp, thought to be seborrheic dermatitis. There was notable exophthalmos and buphthalmos of the right eye. Roentgenograms showed normal optic foramina. An intravenous pyelogram was normal. Further examination of the right eye showed an enlarged, cloudy cornea measuring 12 mm in diameter. The left corneal diameter was 9.5 mm. The lateral portion of the right upper eyelid was floppy, suggesting the presence of an early plexiform fibroma. The intraocular pressure in the right eye was substantially elevated, measuring 35 mm Hg. Pressure in the left eye was not initially measured; but subsequently, under anesthesia, it was found to be within normal limits at 10 mm Hg. Gonioscopy showed open angles bilaterally. On funduscopic examination, a large vascular hemangiomatous lesion was seen in the periphery of the right eye. The right optic disc was normal in color, but the cup-disc ratio of 0.5 (normal < 0.3) indicated a glaucomatous condition, especially

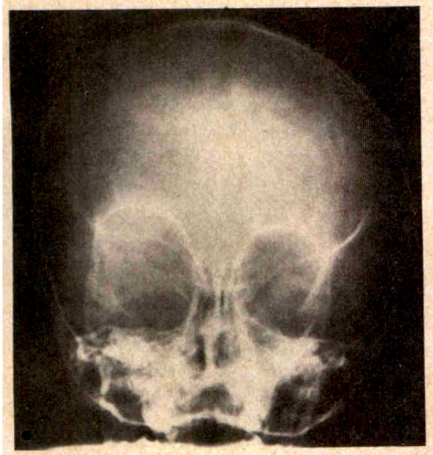

Fig 3.—Notable orbital asymmetry, with right orbit considerably larger than left.

in view of the normal left optic disc, which showed no cupping. Because of the elevated intraocular pressure, enlarged cloudy cornea, and glaucomatous optic cupping, treatment was begun with 4% pilocarpine, 1% epinephrine hydrochloride, and acetazolamide. She was discharged at 4 weeks of age, with a diagnosis of congenital glaucoma secondary to neurofibromatosis.

She was hospitalized for further evaluation at 10 months of age. Results of the physical examination were normal except for the presence of five cafe-au-lait spots distributed on her back and right leg and for notable proptosis of the right eye (Fig 1). Roentgenograms showed progressive enlargement of the right foramen and right superior orbital fissure consistent with the presence of an optic mass. A pneumoencephalogram showed no gross abnormalities, but visualization was incomplete and the presence of an optic mass could not be excluded.

At 27 months of age, a computerized tomographic study showed a mass lesion in the posterior aspect of the right orbit that extended beyond the confines of the optic nerve (Fig 2). At 31 months of age, skull roentgenograms showed an enlarged, deformed right orbit (Fig 3). Surgical exploration showed a plexiform neurofibroma involving most of the right orbit, including the globe, superior rectus and levator muscles, and retrobulbar area. It was decided that removal of the tumor would require complete orbital exenteration; and because of the presence of some vision in the affected eye, such a procedure was not considered at that time. At 44 months of age, vision in the right eye was noted to be minimal. Surgical removal was considered for the future when orbital growth would be more complete and she could more easily be fitted with a prosthesis. At 4 years, 9 months, of age, the right eye was still glaucomatous with only minimal vision present (3/200). Her growth and development were normal as were the results of her physical examination, except for the obvious deformity of the right eye and the cafe-au-lait spots. She is currently being treated with 1% epinephrine.

Comment

Congenital glaucoma may be associated with a variety of systemic disorders such as neurofibromatosis, Sturge-Weber syndrome (nevus flammeus with glaucoma), and Lowe's syndrome (glaucoma associated with cataract, mental deficiency, muscular dystrophy, and renal disease).[5] Increased intraocular pressure usually becomes apparent in the first year of life. Presumably, the mode of pathogenesis for glaucoma is obstruction of the aqueous humor outflow channels by the presence of an intraocular mass. When the intraocular pressure is increased in an infant, the elastic outer coats of the eye distend, leading to an enlarged eye. The descriptive term "buphthalmos" has generally been applied to such an eye. The rarity of the condition increases the likelihood of missing the diagnosis in the early stages.[6]

Although the first clinical signs of neurofibromatosis are usually multiple cafe-au-lait spots,[1] ocular signs may predominate to such an extent that the problem can freqently be recognized by simple inspection of the child in combination with a positive family history. Definitive diagnosis most commonly occurs when parents recognize a growing mass that leads them to seek medical attention.

Glaucoma in newborn infants secondary to neurofibromatosis undoubtedly exists more than is generally recognized. It is usually, however, only after several weeks or months, when the infant's affected eye has enlarged to a point where the condition is obvious, that the diagnosis is more readily made. We would urge that this clinical problem be considered when encountering small infants, even as newborns, with eye abnormalities and family histories similar to those described in this report.

Richard Latchaw, MD, of the Department of Radiology at the University of Minnesota, Minneapolis, prepared the illustration of the computerized tomographic study.

Review

Bacterial Immunizations

H. Robert Harrison, PhD, MD, MPH, Vincent A. Fulginiti, MD

In the past two decades, viral vaccines have captured the interest and imagination of scientist and practitioner. The elimination of smallpox and the potential control of polio, measles, and other childhood diseases have overshadowed the slower progress with bacterial vaccines. This review will place bacterial vaccines in perspective and outline theoretical and practical aspects of their development and usage.

HISTORY

Bacterial "vaccinology" does not have an historic origin analogous to Jennerian vaccination. The first scientific attempt was Pasteur's experiments with veterinary diseases.[1] Aged cultures of attenuated fowl cholera and anthrax bacilli were used to immunize susceptible animals. In both instances, these animals became remarkably resistant to challenge by virulent organisms. In parallel, and in sequence, others explored the use of killed and attenuated bacteria in the prevention of human disease. Koch discovered cell-mediated immunity during a search for tuberculosis vaccine. Von Behring and Kitasato discovered diphtheria antitoxin and passive immunity during primitive studies of diphtheria immunization.

The first generally used bacterial vaccine for man was a type of typhoid vaccine.[2] In 1884, Solomon and Smith demonstrated that heat-killed hog cholera baccillus (a salmonella) protected pigeons against virulent challenge. Pfieffer and Cole immunized two humans in 1896 with heat-killed typhoid bacilli. Almrath Wright drew on these two events to develop an effective typhoid vaccine in 1898.

At the time, typhoid was more devastating than war. It killed 5,000 each year in England and 35,000 each year in the United States. The case-fatality rate ranged from 10% to 30%; seven times as many soldiers died from typhoid as did from battle injuries in the Spanish-American War.

Wright systematically tested a heat-killed typhoid vaccine until 4,000 Indian Army volunteers had received it. Reactions to the vaccine were severe, but protection was striking; mortality decreased from 14% to 2%. Despite problems with politics and excessive vaccine reactivity, additional large-scale studies were carried out during World War I. Among 1,125,000 immunized British troops, only 7,500 cases of typhoid occurred, with 266 deaths. In contrast, during the South African war, 73,633 unimmunized soldiers contracted typhoid and 10,144 died.

This early success encouraged others to explore the use of cholera and plague vaccines and opened the door to modern bacterial vaccinology. Reactions to all of the bacterial vaccines were severe, but protection against disease was striking. Despite the reactions and despite technological accidents yielding virulent or contaminated vaccines, progress in development continued, culminating in vaccines against diphtheria, tetanus, pertussis, and other bacterial diseases. For a full review of this fascinating era in microbiology and medical and human history, the reader may consult the references by Parish.[1,2]

THE IMMUNOLOGY OF BACTERIAL INFECTION

Despite broad advances in the science of immunology, our knowledge of bacterial immunity is primitive in some areas, and only modestly sophisticated in others. This section explores what is known of bacterial immunity and its relationship to vaccines, sera, and γ-globulin.

Bacterial Infection: Pathogenesis

Bacteria produce disease[3,4] directly by invasion or indirectly through the elaboration of substances injurious to the host. Virulence of a specific organism is related to its capacity to establish itself, penetrate tissue, or produce toxins, enzymes, etc.

To successfully infect a host, a sufficient quantity of bacteria must find access to fertile sites in the host that provide nutrients for replication and that are not inimical to bacterial survival. Having established a locus for replication or metabolic activity, the bacteria can then produce disease by direct tissue injury or indirect effects. Invasiveness is an important characteristic of some virulent bacteria. If, in addition, the organism has survival mechanisms that rebuff human defense systems and elaborates elements destructive to cells, systemic

disease and metastatic infection results.

Salmonellae provide a model for these attributes. A sufficient infective dose must be ingested or no infection is established. Some salmonellae have high potential for invasion (*Salmonella typhi*) and produce bacteremia with little or no gastrointestinal (GI) disturbance. Others are virtually noninvasive, producing most of their effects locally in the intestine, with resultant gastroenteritis.

• Specific bacterial metabolic products influence survival of the bacteria. Toxin production often damages tissue, resulting in favorable circumstances for growth. Enzymes may allow bacterial penetration deeper into tissues, with spread and replication. Successful survival in the blood results in dissemination and organ-specific infection.

Host Responses

The array of responses[4] to bacteria are numerous and varied. Most nonspecific responses will not be extensively considered here, but it must be remembered that they contribute heavily to prevention of bacterial colonization and local growth.

Nonspecific Mechanisms

The only nonspecific factors of importance to our discussion are the phagocytic cells and chemical substances that interact with bacteria and phagocytes. The reticuloendothelial system has the capacity to ingest and destroy bacteria. Circulating phagocytes, wandering tissue macrophages, and fixed tissue phagocytes all play a role. Random contact occurs in the absence of specific immunity; phagocytosis is enhanced by naturally occurring opsonins. This primitive defense system is limited in its effectiveness, and the host depends on specific immunity to facilitate bacterial elimination and control.

Specific Immunity

There are two elements of specific immunity involved in bacterial defense: antibody-mediated and cell-mediated immunity.

Antibody Immunity.—Antibody synthesis is stimulated by antigenic structures on the surface of bacteria, by substances elaborated by the bacterium, or by internal structures made available during bacterial disintegration. In general, IgM is produced first; and in the normal sequence, it gives way to IgG antibody, which becomes the principal immunoglobulin involved in antibody activity.

IgM seems to be a more primitive response both phylogenetically (it develops first in lower species) and ontogenetically (it is the first immunoglobulin produced by the human fetus). It is a more efficient mediator of opsonization than IgG, rendering the bacterium more susceptible to phagocytosis. Since the earliest contact after infection is between bacteria and phagocytic cells, the early presence of IgM-antibody seems to facilitate this control mechanism. IgM is also more efficient than IgG in killing bacteria and in agglutinating them. On the other hand, IgG antibody functions best in precipitation, thus dealing efficiently with chemical products of bacteria. Neutralization of toxin, enzymes, and other bacterial products further counters the virulence of bacteria, aiding in their elimination.

Finally, IgA production may be stimulated and provides effective barrier functions at mucosal surfaces. Many bacteria are relatively or absolutely noninvasive but possess powerful exotoxins that cause disease. Control of these organisms involves secretory IgA present in high concentration on endothelial surfaces as well as local inflammation and leakage of plasma IgM, IgG, and cellular elements.

All of the aforementioned events describe the initial encounter between bacterium and host; subsequent contact rapidly calls forth IgG (and possibly IgA) antibodies that may prevent even the initial virulence of organisms by containing their growth in the GI or respiratory tract and by neutralizing elaborated noxious substances. This anamnestic response can result in no infection on second contact or the limitation of infection to trivial disease. Thus, inhaled pneumococci may be attacked by specific secretory IgA previously stimulated. If lymphatic or bloodstream invasion occurs, rapid control may be achieved by preexistent and readily recalled specific IgG antibody. The child may experience no disease or mild respiratory symptoms instead of pneumonia and bacteremia.

Cell-Mediated Immunity (CMI).—Much less is known of the role and importance of CMI in recovery from and resistance to bacterial infection. The bacterial model most often cited is tuberculosis, in which CMI is readily demonstrable and related to pathogenesis, recovery, and immunity. For more common bacteria, there is less information although a body of data is growing that suggests that CMI responses to bacteria do occur.

RECAPITULATION

Bacterial contact calls forth an array of nonspecific and specific defenses on the part of the host. Outcome of bacterial-host contact is dependent on the efficiency, specificity, and speed of these responses balanced against the virulence of the bacterium. In normal individuals, most encounters result in trivial or no disease; only rarely does clinical symptomatology of an important degree occur, and even less commonly does the host die. Individuals who lack individual components of the defense system are susceptible to serious, persistent, recurrent, and even lethal infections dependent on the degree and specificity of the defect and the chance encounter with appropriate bacteria.

IMMUNIZATION AGAINST BACTERIAL INFECTIONS

General Principles

Effective vaccines are dependent, in part, on precise knowledge of natural immunity. Often, the degree of protection afforded by a given vaccine parallels our insight into the pathogenesis of disease and host defenses. For example, knowledge that tetanus is produced solely by the effects of an exotoxin of *Clostridium tetani* enables us to use vaccine that evokes antitoxin rather than one directed at the whole organism. Further, exogenous antitoxin can be used in prevention and treatment. On the other

hand, little is known of pertussis immunity, with the result that a crude vaccine is used that provides only 75% to 85% protection and includes many bacterial components that are both harmful to the host and of unknown immunologic benefit. Further, pertussis immune globulin seems of no benefit in either prevention or treatment.

All available bacterial vaccines are given by injection, a method that bypasses the natural mode of infection. This results in a disparity between stimulation of systemic immunity and topical immunity; the latter does not develop and this limits the vaccine's effectiveness in control of initial stages of infection. Current investigative interest focuses on mimicry of the normal route of infection, with the anticipation of improved protection.

SPECIFIC VACCINES

Diphtheria

Principles of Immunity.—*Corynebacterium diphtheriae* produces disease by the establishment of a focus of infection (respiratory tract or skin) and the elaboration of a potent exotoxin. The exotoxin is destructive to all cells, but myocarditis, tubular necrosis, and myelin degeneration are most obvious in the human.[5] Free toxin and that attached to cell-surface receptors can be neutralized by antitoxin; intracellular toxin is not affected. Establishment of infection is partially dependent on the organism's capacity to produce toxin; this results in local tissue destruction allowing survival and growth of the bacterium.

Preexisting antitoxin in the human results in little systemic disease; that which occurs is mild and nonlethal.[6] Administration of antitoxin to a person already infected controls further development of toxin-induced effects and neutralizes some of the toxin already circulating and present on cell surfaces. Routine, active immunization practice is aimed at immunizing all individuals early in life and at sustaining immunity by periodic additional doses of vaccine.[7]

Vaccines Available.—Diphtheria toxoid is prepared singly or in combination with other antigens.[8] It is formaldehyde-inactivated toxin produced by the PW-8 strain. It also is manufactured as a fluid preparation and as an adjuvant vaccine containing alum. The fluid vaccine has no true advantages and will not be further considered.

A single dose of 0.5 mL of any of the vaccines contains sufficient toxin to be immunogenic. Full immunologic response occurs only with a complete primary series and a booster one year later.[9] Subsequent immunity is maintained by periodic booster doses as outlined in the text. The goal is to maintain circulating antitoxin levels at 0.02 unit/mL of serum or higher.

Diphtheria toxoid, adsorbed.—It contains 7 to 25 IU of toxoid in 0.5 mL of vaccine.

DT (Pediatric) Diphtheria-Tetanus Toxoids, Adsorbed.—This contains 7 to 25 IU of diphtheria toxoid and tetanus toxoid. It is for use only in children less than 7 years old.

Td (Adult) Tetanus-Diphtheria Toxoids, Adsorbed.—This contains full amounts of tetanus toxoid plus not more than 2 IU of diphtheria toxoid. This is for use in primary and booster immunization in anyone 7 years of age or older.

Diphtheria-Tetanus-Pertussis (DTP).—This contains full doses of diphtheria and tetanus toxoid plus pertussis vaccine. It is intended only for immunization of infants and young children.

Schedules.—Diphtheria immunization is ordinarily accomplished as DTP immunization at 2, 4, 6, and 18 months of age.[10] Another booster is given at school entry and every ten years thereafter as Td. The reduction in diphtheria toxoid concentration in Td boosters is mandated by the high reactogenicity of toxoid in older individuals.

For individuals unimmunized in infancy but less than 7 years of age, TD (DT, pediatric) may be substituted for DTP in the same schedule. For unimmunized individuals older than seven years, three doses of Td with a booster one year later and every ten years thereafter suffices.

Immunized close contacts of patients with clinical diphtheria should receive a booster dose of the appropriate vaccine for their age. Unimmunized contacts can be immediately protected by antitoxin plus antibiotics with concurrent immunization, with special attention to booster doses to insure immunity.[11] Recovery from clinical diphtheria does not confer immunity; immunize patient as appropriate for age.

Side Effects and Adverse Reactions.—The usual use of multiple antigen vaccines makes evaluation of the side effects of diphtheria toxoid difficult. Much of our information derives from earlier experiences when this vaccine was used singly and fails to account for recent technological changes in the preparation and purification of toxoids.

Local tenderness, erythema, and induration occur in as many as 54% of recipients.[12] Serious side effects are uncommon in infants and children; they are more frequent among adults. For this reason, DT is used in individuals less than 7 years old and Td in those older than 7 years. Rare reports of isolated instances of hypersensivity have been recorded.

Tetanus

The etiologic agent of tetanus is *Cl tetani*, which is an anaerobic, spore-forming, Gram-positive rod; it exists in nature as an extremely resistant spore. It is introduced into an area of injury in that form; within the wound, the conversion from spore to the toxin-producing vegetative organism is dependent on a host of local factors.[13,14] All the clinical features of tetanus are produced by the activity of the soluble exotoxin, tetanospasmin,[15] which is produced by the vegetative form of *Cl tetani*; the organism itself causes no disease.

Principles of Immunity.—There is no natural immunity to tetanus.[16] Immunization strategy uses the observation that clinical immunity depends on the presence of circulating antibody against tetanospasmin. Thus, prophylaxis is achieved with either active stimulation of antibody, passive antibody transfer, or a combination of both. The basis for active immunization is formaldehyde denatured tetanospasmin (tetanus toxoid), which is antigenic but nontoxic. Production of

antibodies to the toxoid renders the patient immune to tetanospasmin.[17]

Vaccines Available.—Tetanus toxoid is available as an aluminum phosphate adsorbed or a fluid vaccine. The fluid toxoid has been used only for booster doses when rapid protection is required,[13] but it induces an antibody response of a much shorter duration.[10] Adsorbed vaccine (and not the fluid form) is antigenic in the presence of passively received antibody[18] and is the only preparation recommended for primary immunization.

Aluminum phosphate adsorbed tetanus toxoid is available as the following: triple antigen (diphtheria-tetanus-pertussis, DTP); diphtheria and tetanus toxoids, adsorbed, pediatric (DT); and tetanus and diphtheria toxoids, adsorbed, adult type (Td). Td contains a smaller dose of diphtheria than DT and is used in those younger than 7 years old for recall and in adults not previously immunized.

Schedules.—Three vaccine schedules have been designed.

Routine Immunization.—Children 2 months to 7 years of age should be given three DTP immunizations intramuscularly at six to eight week intervals, with a fourth injection one year after the third dose.

Children More Than 7 Years Old and Adults Not Previously Immunized.—Two doses of Td vaccine should be given intramuscularly two months apart, with a third dose given six to 12 months later. It should be noted that the first dose of vaccine produces little or no increase in antibody titer. Antibody levels increase after the second and subsequent doses. The accepted protective level of circulating toxoid antibody is 0.01 unit/mL.

Booster Doses.—The decay rate of endogenous tetanus antitoxin is low in both children and adults.[19] There is also a strong correlation between the occurrence of reactions to booster doses and the patient's circulating tetanus antitoxin levels. To minimize both acute hypersensitivity and Arthus-type reactions, it is recommended that booster doses be given intramuscularly every ten years. If a dose is administered sooner as part of wound management, the next routine booster is given ten years from that time.

Side Effects and Adverse Reactions.—Local and systemic reactions to tetanus toxoid are uncommon in children.[17] These can be categorized as urticarial, with or without angioneurotic edema and not necessarily limited to the site of injection, and as Arthus type (the most common). Rarely, delayed-hypersensitivity reactions may occur. Evidence now suggests that too many injections may lead to a qualitative change in the spectrum of antibodies produced, with an increasing frequency of those of reaginic type.[20]

Pertussis

Principles of Immunity.—We do not know why children recover from pertussis nor which antigens evoke which immunologic responses related to protection.[21] Although much is known of the antigenic composition of *Bordatella pertussis* and some information is available on specific antibody responses, no conclusive and noncontroversial link between immunity and protection has been made.

Antibodies of various types have been described after natural infection and immunization in animals and man.[21] No one class of antibodies nor one type of specific antibody action seems to correlate perfectly with recovery and immunity. Studies of cell-mediated immunity and topical respiratory immune mechanisms are still preliminary and have shed little light on this critical issue.

Thus, we still immunize against pertussis without much information. The best-performed studies here and abroad demonstrate efficacy for whole-bacterial pertussis vaccines, which are partially contingent on the specific serotypes included and the potency of the particular preparation.[22]

No other vaccine has evoked as much controversy concerning its efficacy vs its side effects and adverse reactions. Even today in England, there are some scientists and practitioners who doubt that pertussis vaccine affords sufficient protection to use it positively in the light of its predictable adverse consequences.[23] An exhaustive review of all the data and arguments is not indicated here.

We conclude that pertussis vaccines as used in the United States offer protection against the disease.[24] This protection is limited in quantity (75% to 85% reduction in the incidence of pertussis in those fully immunized as opposed to unimmunized children) and in duration (immunity wanes after the primary series and boosters). Pertussis can be a devastating disease, especially in the very young; and even this degree of protection is desirable. Adverse effects will be considered later, but they further limit the value of current vaccine usage and indicate the need for development of new vaccines.

Obviously, the need is for more precise definition of specific immunity and for design of a vaccine that yields maximum protection at little or no risk. Such efforts are underway, with components of the organism as the primary antigen.

Vaccines Available.—Pertussis vaccine can be administered alone or in combination with diphtheria and tetanus toxoids. It is available as a plain preparation or adsorbed to alum. The adjuvant vaccine contains 4 protective units/0.5 mL dose whereas the plain vaccine contains somewhat more antigen. There is no rationale for the use of plain pertussis vaccine; it offers no immunologic advantage nor is it safer. All pertussis vaccines whether alone or in combination with other antigens contain whole bacteria that have been inactivated.

Plain Pertussis Vaccine (Without Alum).—It is useful in epidemics for rapid protection. Administer three intramuscular (IM) doses of 0.5 mL (4 National Institutes of Health [NIH] units) each, at monthly intervals.

Adjuvant Pertussis Vaccine (With Alum, Aluminum Phosphate, or Aluminum Hydroxide).—Give three IM doses of 0.5 mL (4 NIH units) each, at monthly intervals, for primary immunization. Within eight to 12 months after primary immunization, whether with plain or adjuvant pertussis vaccine, a booster dose of adjuvant vaccine should be used.

DTP.—This is a combination of the bacterial suspension of pertussis plus

the two toxoids. It is usually distributed in multiple-dose vials. Give three IM doses of 0.5 mL each, administered at bimonthly intervals. A booster dose should be given at 18 months of age and again at 4 to 5 years.

Schedules.—Pertussis vaccine is designed primarily for use in infancy and early childhood.

Primary Immunization in Infancy.—Pertussis vaccine is usually administered in combination with diphtheria and tetanus toxoid as DTP.[10] Each 0.5-mL dose of DTP contains 4 units of pertussis vaccine.

Three doses of DTP (a total of 12 units of pertussis antigen) are given intramuscularly at two-month intervals beginning at 2 months of age. In areas of high endemicity or during epidemics, it may be desirable to start immunization earlier. The vaccination is begun at 4 to 6 weeks of age, and three doses one month apart are given. Rarely, in severe epidemics affecting extremely young infants, pertussis immunization can be started in the first few days or weeks of life, but this is seldom necessary. After primary immunization, a booster is given one year later.

Recall Immunization.—Routine recall boosters are suggested when the child enters school. If pertussis is prevalent in adolescence, a half dose can be given to children older than age 7 years and to adults requiring booster doses.

Special Circumstances.—After intimate exposure to pertussis or during epidemics, children younger than 7 year of age can receive a 0.5-mL dose, and older patients should receive 0.25 mL of either DTP or pertussis adsorbed vaccine, depending on age.

In children with neurologic diseases, one wishes to protect against pertussis but also to avoid the toxicity of pertussis vaccine on the CNS. Most experts advise using pertussis adsorbed vaccine alone and dividing the needed 12 units among several small doses. One such regimen would be to use 0.1 mL (approximately 1 protective unit) given monthly until all protective units are administered. Others divide a 0.5-mL dose in half, for six injections. Many experts suggest that unchanging neurologic disease in infancy is not a contraindication to full doses and the usual schedule of pertussis immunization that developers advocate. If, for example, the child has congenital hydrocephalus without convulsive disorder or without a changing pattern of neurologic deficit, it would be perfectly alright and even desirable to proceed with the pertussis immunization at the usual time with the usual doses and the usual vaccine. On the other hand, if a child has a convulsive disorder or a changing encephalodegenerative disease, it would be unwise to attempt any pertussis immunization at all. Although fractional doses are widely used for children and infants with neurologic disease, we believe it is neither necessary nor desirable.

In children with previous reaction to pertussis vaccine that are of severe systemic or CNS character, *no further pertussis vaccine should be given.* If the reaction has been local or systemic of mild degree, pertussis vaccine can be separated from DTP and the aforementioned procedure followed. On the other hand, many practitioners will give full doses of DTP in these circumstances. There is no evidence that reactions will increase in severity with subsequent doses. However, it is important to emphasize that when any CNS symptoms follow the administration pertussis vaccine, further pertussis vaccine should not be administered.

Side Effects and Adverse Effects of Immunization.—Both local and systemic adverse effects may occur with pertussis vaccine.[12,22,25-27] Local reactions consisting of pain, induration, and redness may occur in as many as 70% of recipients. Occasionally, a sterile abscess may develop at the injection site; but with modern, careful aseptic technique, this is a rare event.

Mild systemic symptoms are also frequent after pertussis immunization. Low-grade fever, irritability, feeding difficulties, and excessive sleepiness have all been reported. More severe reactions consisting of high temperature alone (greater than 40 °C) are encountered in 1% to 5% of pertussis vaccine recipients.

Convulsions, with and without fever, have been encountered with variable frequency after pertussis immunization. Recent data suggest that the incidence is 1/1,000 to 2,000 immunizations. Others have estimated less common frequencies in the range of 1/3,000 to 50,000 immunizations. As many as 50% to 80% of patients with convulsions will also have fever. It is difficult to be certain of the relationship between fever and the convulsive episode.

Children with a history of convulsions are extremely likely to have convulsions at the start of pertussis immunization. Children who react to pertussis vaccine with a convulsive episode probably have an even greater risk of convulsion after subsequent immunization. The difficulty of all statistical evidence of convulsions in association with pertussis vaccine is the background incidence of convulsions in the age group that receives DTP. As many as 1% of children in this age group may have convulsions unassociated with pertussis immunization. However, there seems to be little question that pertussis immunization does increase the frequency above this background rate and that in the aggregate it is responsible for convulsive episodes. A more serious complication of pertussis vaccine is the encephalopathy syndrome. Clinical manifestations range from sudden collapse through persistent screaming to frank neurologic degenerative disease and even death. Sudden collapse may be due to a shock-like syndrome possibly associated with acute anaphylaxis or may be a manifestation of acute encephalitis. The "persistent crying" syndrome has been anecdotally described for a number of years; more recently, a comprehensive study in Los Angeles by L. Baraff, MD, and J. Cherry, MD (unpublished data, 1977 to 1979) suggested that persistent crying may be secondary to CNS irritation. As many as 5% of their DTP recipients had persistent crying and 0.2% had collapse. Others have reported an even higher incidence of these reactions.

The estimates of frank encephalopathy after pertussis vaccines have ranged from as many as 1/6,000 doses to as few as 1/1,000,000 doses.[25-28]

Many experts are of the opinion that an incidence of 1/50,000 to 100,000 is the most likely reaction rate in the United States. As of this writing, the precise incidence is unknown.

The outcome of encephalopathy syndromes may range from almost an immediate recovery through residual neurologic damage of varying degree to death. One British study concludes that the risk of residual brain damage from pertussis immunization is 1/300,00 immunizations. Once again, difficulty in ascribing a particular encephalitic reaction to pertussis immunization is highlighted by nonpertussis encephalitic syndromes occurring in the age group receiving vaccine. Less commonly encountered reactions after pertussis immunization are acute anaphylaxis and postimmunization thrombocytopenia.

Pneumococcus

Principles of Immunity.—The pneumococcus (*Streptococcus pneumoniae*) depends for its pathogenicity on a polysaccharide capsule that renders it resistant to phagocytosis and destruction. The human host, in turn, responds to infection with production of antibody to this polysaccharide capsule. Recovery from pneumococcal infection is associated with the presence of antibody to the capsular polysaccharide. Immunity is type specific: antibody is directed against only the polysaccharide of the invading organism, and it is ineffective against the other 83, or more, known types of pneumococci.

Vaccines Available.—Vaccination with purified combined pneumococcal polysaccharide antigens has been demonstrated to elicit antibody and protect against natural disease from organisms of the capsular types included in the vaccine.[29,30] Indeed, a combined polysaccharide vaccine similar to the currently available one was licensed and produced in this country from 1945 to 1947. However, the availability of effective antibiotics against the pneumococcus led to the discontinuation of vaccine production.

The continuing high mortality from pneumococcal disease despite appropriate treatment, plus the emergence of resistant pneumococci, has led to a revival of interest in pneumococcal vaccine. The 14-valent polysaccharide vaccine now available contains, per 5-mL dose, 50 μg of purified capsular polysaccharide for each of the 14 serotypes (American types 1, 2, 3, 4, 6, 8, 9, 12, 14, 19, 23, 25, 51, and 56) causing at least 80% of serious pneumococcal disease in the United States.[31] The carrier is isotonic saline solution containing 0.25% phenol as a preservative.

Schedules of Immunization.—Although experience with the polyvalent vaccine in adults has been highly favorable, there is limited information for children. So far, studies of children indicate that those less than 2 years of age exhibit unsatisfactory serologic responses to a single dose of vaccine.[32] No booster effect has been seen so far in adults, and the effect of a booster in children is unknown. In a small group of children older than 2 years with sickle cell anemia and splenectomy, the incidence of bacteremic pneumococcal disease seemed to be reduced after immunization with a single dose of an 8-valent vaccine.[33]

The data currently available permit the vaccine to be recommended for use in children older than *2 years of age* who are at risk for severe or life-threatening pneumococcal disease. These include children with sickle cell anemia, those with splenectomy,[34] and perhaps those with Hodgkin's disease, prior to splenectomy or treatment.[34] In addition, children with nephrotic syndrome should be considered as candidates for inoculation.[35] In all cases, a single 0.5-mL dose given subcutaneously or intramuscularly is recommended. This recommendation may change with continuing experience with children.

Side Effects and Adverse Reactions.—Children who receive the vaccine may experience pain, erythema, and induration at the site of injection. A small number may have a slight temperature elevation. No substantial reactions have been noted.

More recent experience indicated that children and adults who have received pneumococcal vaccine may experience severe and even fatal bacteremia with pneumococci included in the vaccine grouping as well as among those strains not included.[36] Those infections that have occurred with strains included in the vaccine seem to occur because the recipient does not respond adequately to that particular antigen. Of course, those infections occurring with strains not included in the vaccine could not have been prevented. The practical meaning of these new data are that children who receive pneumococcal polysaccharide remain susceptible to bacteremia and therefore must receive ongoing prophylaxis and prompt, vigorous therapy of any infectious episode. In general, this means continuous ampicillin sodium therapy for children less than 4 years of age and penicillin prophylaxis for children older than 4 years. One should also remember that asplenic children may experience infection with organisms other than the pneumococcus, thus each infectious episode should be treated as potentially bacteremic and lethal.

Meningococcus

Principles of Immunity.—Circulating antibodies to meningococcal cell-surface antigens constitute a major defense against systemic meningococcal disease.[37,38] In the last ten years, there has been an attempt to protect humans from meningococcal disease through the use of active immunization with group-specific purified capsular polysaccharide vaccines. Numerous large-scale studies have shown that in adults and older children, group A and group C vaccines can prevent infection with meningococci of these serotypes.[39-41] The group B polysaccharide is poorly immunogenic,[42] so that efforts with group B prophylaxis are being directed at a vaccine based on protein rather than polysaccharide components of this organism.[43]

More than two-thirds of all meningococcal disease occurs in people younger than 20 years old.[44] Group A infections are uncommon in this country; group B and C have their highest age-specific attack rates in infants and young children. In recent years, disease in civilians has occurred primarily as isolated cases or, occasionally, as small clusters. Secondary cases occur preponderantly in household contacts.[44]

Vaccines Available.—Two meningococcal polysaccharide vaccines, monovalent A, and monovalent C, are of importance. Each monovalent dose contains 50 μg of a freeze-dried, group-specific purified polysaccharide (polymers of particular neuraminic acids) that is reconstituted with isotonic saline solution containing 1:10,000 thimerosal as a preservative. The injection is given subcutaneously.

Schedules and Indications.—There is much debate about the usefulness of meningococcal vaccines in pediatric practice. They are expensive, relatively ineffective in young children, and the duration of clinical immunity conferred is still unclear. Recent evidence suggested that most infants older than 12 months of age will have protective levels (2 μg/mL) of antibody develop after a dose of monovalent A vaccine.[45] Clinical immunity seems to last at least two years. Although group C vaccine has been used successfully in military recruits, children younger than 6 years old show a variable response, with many, especially those younger than 2 years, achieving nonprotective antibody levels.

In our country, meningococcal disease is uncommon, and it occurs primarily in the extremely young, in whom the vaccines are least effective. Vaccination should be offered to military recruits, to hospital personnel regularly, and to household contacts (older than 1 year of age) of patients with the disease.[44,46] In addition, some form of antimicrobial prophylaxis (rifampin is recommended) should be given these contacts during the brief period (approximately five days) before immunity develops. Serogroup-specific vaccine may also be used to control a community outbreak caused by group A or C meningococcus.

In areas where meningococcal outbreaks are common, such as parts of Africa, a much stronger case for routine immunization can be made. However, that discussion is outside the scope of this article. Travelers from the United States to endemic areas of group A and C disease may benefit from immunization.

Side Effects and Adverse Reactions.—Adverse reactions are infrequent and mild, consisting of localized erythema, pain, and induration lasting one to two days.

Cholera

Principles of Immunity.—Cholera is caused by *Vibrio cholerae* and results in a devastating fluid-loss diarrhea. Immunity to the disease probably results from secretory mechanisms, possibly secretory IgA-specific antibody, at the intestinal level. Thus, the results of parenteral administration of cholera vaccine are understandably disappointing.[47] Only 60% to 80% protection is afforded, for short periods, often less than six months.

Vaccines Available.—Current vaccine consists of a combination of several strains of phenol-inactivated *Vibrio* whole bacterial cells. It is administered subcutaneously or intramuscularly.

Schedules of Immunization.—*Only children older than 6 months should receive the vaccines.* Primary immunization consists of two doses of vaccine (intramuscularly or subcutaneously) given one week to one month or more apart. Specific dose for age is: 6 months to 4 years, 0.2 mL; 5 to 10 years, 0.3 mL; 10 years and older, 0.5 mL. An identical dose is given as a booster six months later.

For children older than 5 years of age, some prefer the intradermal route to minimize reactions; the intradermal dose is 0.2 mL for both primary and booster doses.

Side Effects and Adverse Reactions.—Tenderness, erythema, and induration for one to two days postimmunization are frequent. In some individuals, fever, malaise, and headache also occur; they are occasionally severe enough to require bed rest for short periods. Reactions of all types are less common with intradermal immunization.

Plague Immunization

Principles of Immunity.—Plague is caused by *Yersinia pestis*. Immunity is presumably related to circulating antibody and immunization seems to be of some benefit.[48]

Vaccine Available.—Heat-killed organisms make up plague vaccine. Use of the vaccine is associated with decreased morbidity and mortality.

Schedules of Immunization.—Plague vaccine is reserved for children traveling to or residing in endemic areas who are at high risk of exposure. Primary immunization consists of three IM injections of vaccine: the first two injections at 30-day intervals, and the third four to 12 weeks after the second. Specific dose for age is as follows, with booster dose at 40% of initial dose:

Age, yr	Primary Immunization, mL	Booster, mL
<1	0.1	0.04
1-4	0.2	0.8
5-10	0.3	0.12
≥10	0.5	0.2

Typhoid

Typhoid is caused by systemic infection with *Sal typhi*. Immunity to typhoid does not seem to be related to the presence of antibodies against the usual antigens of *Sal typhi*.[49] The titers of O, H, or Vi antigens are unrelated to resistance to infection. In experimental disease, the macrophage seems to be a major component of resistance to challenge with typhoid bacilli. Antigens of the organisms seem to activate macrophages, enabling them to resist challenges with living virulent organisms. There is some speculation that cell-mediated immunity may play an important role in typhoid resistance and recovery from infection.

Vaccines Available.—Acetone-killed typhoid vaccine is preferred by many and consists of inactivated, whole bacteria and fragments. Acetone-killed typhoid vaccine should not be given intradermally.

Schedules of Immunization.—Typhoid vaccination is no longer recommended routinely for persons living in the United States. Selective immunization is suggested for the following categories: persons with intimate exposure to a documented typhoid carrier; and travelers to epidemic or endemic areas. Typhoid vaccine is not necessary for persons in an area of natural disaster or for those attending such activities as summer camps. The vaccine protects 70% to 90% of recipients against low-dose exposure. Ordi-

narily, protection against ingestion of lightly contaminated materials such as water is achieved, whereas protection in situations where heavily contaminated foodstuffs are involved is usually not obtainable.

Children younger than 10 years of age and older than 6 months of age should receive two 0.5-mL doses subcutaneously, four or more weeks apart. Booster doses should be given at least every three years for continued exposure. Physicians who use nonacetone-killed vaccine often give 0.1 mL intradermally as the second dose for children of all ages. Acetone-killed typhoid vaccine should not be given intradermally.

Side Effects and Adverse Reactions.—Typhoid immunization may cause discomfort at the site of injection, often accompanied by fever, lethargy, headache, and myalgia. On occasion, the reaction is severe enough to require bed rest. Regional lymphadenopathy has also been observed.

Anthrax

The agent of anthrax, *Bacillus anthracis*, is endemic in certain parts of the world. Exposure in this country is primarily an occupational hazard: workers who process hides, hair, bone, wool, and animal product fertilizer; veterinarians; and agricultural workers who handle infected animals are at risk.[50,51] Anthrax is infrequent and sporadic; rare, nonoccupational cases have occurred in home craftsmen working with contaminated yarn. In 1978, six cases of human cutaneous anthrax were reported, four in industrial settings and two in agricultural ones.[52]

Vaccine Available.—The vaccine is a cell-free, alum-precipitated antigen prepared from sterile culture filtrates in which the Rl-NP mutant of the Volum strain of *Bac anthracis* has grown.[53] This mutant is nonproteolytic and unencapsulated.

Schedules of Immunization.—Vaccination is reserved for those at high risk for exposure. An antibody response may be expected in anyone older than 6 months of age. Three subcutaneous doses of 0.5 mL are given at two to three week intervals, with an annual 0.5-mL booster.[54]

Side Effects and Adverse Reactions.—Reactions include local edema, induration, warmth, tenderness, and pruritus, with occasional systemic malaise.[54] Immunization of contacts of cases is unnecessary, and immunization of children would almost never be indicated.

Tuberculosis

Principles of Immunity.—Tuberculosis is caused by *Mycobacterium tuberculosis*. Although the disease has shown a continuous decline during the past century, pockets of infection remain within our population. Tuberculosis is still encountered in children in urban ghetto areas as well as among Native American Indians both on the continent and in Alaska. States bordering on Mexico also encounter instances of tuberculosis in children and in immigrants and migrants from Mexico.

Immunity to tuberculosis is a complex phenomenon but rests primarily on development of cell-mediated immunity, manifest as a delayed hypersensitivity reaction to tuberculin. Long before sophisticated understanding of the immunology of tuberculosis was available, a living attenuated strain of *M bovis* was developed by Calmette and Guérin at the Pasteur Institute in France. It was first utilized in 1921 and has been the source of considerable controversy ever since.[10,55-57]

Vaccines Available.—The official designation BCG is used for strains of vaccine developed from the original isolate of Calmette and Guérin. There are many BCG vaccines available today. They vary in their effectiveness and in the reactions they evoke as well as in their capacity to prevent tuberculosis.

Currently available vaccines in the United States are only distantly related to the original isolate, having undergone additional culture passages and changes in the technology of vaccine preparation and preservation.[58] Current vaccines are freeze dried and are attenuated living bacteria tested both for safety and potency. Current vaccines have not been demonstrated to be effective. Efficacy is only inferred from prior experiments and experience with older vaccines both here and abroad.

Schedules for Immunization.—BCG immunization should be seriously considered for the following groups: (1) infants who are skin-test-negative, but who are repeatedly exposed in a household to individuals with pulmonary tuberculosis; (2) individuals and groups in whom tuberculosis is prevalent and for whom health measures to contain or control the disease are not readily available; and (3) tuberculin-negative health workers who are at increased risk of repeated exposure.[58,59]

Since children with a positive tuberculin skin test should not receive BCG, prior tuberculin testing must be done. In infants younger than 2 months of age, prior tuberculin testing is unnecessary, particularly if the infant has not been exposed to tuberculosis. In some vaccine campaigns, such as those conducted by the World Health Organization, prior tuberculin testing has not been done.

BCG should not be given to individuals who may have immunodeficiencies or are receiving immunosuppressant drugs or who have skin infections or thermal burns. BCG has been used for malnourished subjects and for newborns, including prematures. These conditions do not seem to be a contraindication if the tuberculosis risk is high although cell-mediated immunity is depressed and BCG dissemination is a possibility.

BCG is usually administered intradermally over the deltoid or triceps muscle. Newborn infants each receive .05 mL, and older infants, children, and adolescents receive 0.1 mL. A multiple-puncture procedure is an alternative method. Further information and equipment are obtainable from the same sources that supply the vaccine, which are indicated in the footnote at the end of the article.

Side Effects and Adverse Reactions.—The most common side effect of BCG is regional lymphadenitis.[60] This complication is important to recognize since the lymph nodes involved may become large, often simulating lymphoma or other more serious lymph node diseases. Rarely, prolonged ulceration at the vaccination site occurs.

Even more rarely, disseminated BCG infection and death can occur among immunodeficient individuals. Osteomyelitis and lupus-like disease have occasionally been observed.

Tularemia

Infection with *Francisella tularensis* causes tularemia. The organism is found in infected wild and domestic animals and in the ticks, flies, and other insects that bite them. Inoculation occurs via skin or conjunctiva directly or by the bites of infected insects. It may also occur via ingestion of contaminated water or of an infected and inadequately cooked animal or via inhalation.[61,62] Infection occurs readily among laboratory personnel working with the organism.[63]

Francisella tularensis is a facultative intracellular parasite; in animals, immunity depends largely on cellular, rather than humoral, mechanisms.[64,65] Even documented infection with virulent organisms does not prevent reinfection.

Immunization is only recommended for persons at high risk of infection, ie, laboratory workers; children almost never require tularemia immunization. The vaccine consists of live attenuated bacteria produced from a colony-type variant of *F tularensis*. Immunization does not prevent entirely, but does reduce substantially, the incidence of typhoidal tularemia.[63] The occurrence of ulceroglandular tularemia remains the same, but the severity of this disease is decreased.

One drop of vaccine is inoculated by multiple punctures. Local inflammation occurs, and healing with scarring and occasional enlargement of regional lymph nodes ensues, but no systemic reaction is encountered. Inoculation of contacts of cases is unnecessary.

THE FUTURE OF IMMUNIZATION AGAINST BACTERIAL DISEASES

Currently used bacterial vaccines are disappointing when viewed in contrast with viral immunization. The future of bacterial vaccines depends on better understanding of natural immunity, exploration of new vaccines, and improved technology. Some exciting trends can be gleaned in current investigative efforts.

Mimicry of the natural *route* of infection offers theoretical immunologic advantage for some bacterial immunization. Local or topical immune mechanisms might be stimulated by living or killed bacteria placed on the respiratory mucosa or ingested, exposing the GI tract. Experience with live polio vaccines and inactivated influenza vaccines suggest that topical antibody production can be stimulated. An experimental attempt at duplicating this phenomenon for bacteria is the intranasal inoculation of purified type-specific group A streptococcal M-protein vaccines that reduces both colonization and clinical illness after challenge with homologous organisms. Oral administration of live, attenuated shigellae has been shown to be effective in reducing the frequency and severity of type-specific disease in endemic settings.

Current cholera vaccines, both bacterial somatic and toxoid, are disappointing in both the degree and duration of immunity produced. Experimental evidence suggests that local antibody is an important component in human immunity. Studies are under way to develop and evaluate the effectiveness of orally administered live and killed cholera vaccines.

Another new idea occurred as the result of the discovery of cross-reacting antigens in seemingly unrelated organisms. For example, certain types of *Escherichia coli* share antigens with *Haemophilus* sp and with meningococci. Asymptomatic infection with the K-100 type of *E coli* stimulates antibody against *H influenzae*, type B. Similarly, K-1 strains of *E coli* induce antibody cross-reaction with the group B meningococcus. Although far from practical use, this line of investigation opens up the possibility of protection by use of an innocuous organism, possibly overcoming the difficulties experienced in current attempts at protection against these imported pediatric diseases.

Development of improved vaccines continues for pertussis, *H influenzae*, and the meningococci, particularly group B. The goal is vaccines for each that are safe and antigenic for the extremely young infant, for whom the risk of disease with these organisms is high.

Attempts to dissect the pertussis organism into antigenic units, which avoid the side effects of current whole bacteria vaccines, are in progress. A protein derivative from the outer membranes of group B meningococcus is being evaluated for adults. A new protein-polysaccharide complex from *H influenzae* has been tested in adults and is available for study in older children. These and other approaches offer the possibility of new and improved bacterial vaccines for pediatric practice in the future.

The vaccine for anthrax is available from the Center for Disease Control, Atlanta, on request. Current BCG vaccine can be obtained from ITR Biomedical Research, University of Illinois Medical Center, 904 W Adams St, Chicago, IL 60607; and Glaxo Laboratories, Ltd, Greenford, Middlesex, England (distributed in the United States by Eli Lilly Co). The vaccine is delivered in a freeze-dried state and should be reconstituted, protected from exposure to light, and used within eight hours of reconstitution.

Nonproprietary Names and Trademarks of Drugs

Ampicillin sodium—*Alpen-N, Amcill-S, Omnipen-N, Penbritin-S for Injection, Polycillin-N for Injection, Principen/N.*
Rifampin—*Rifadin, Rimactane.*

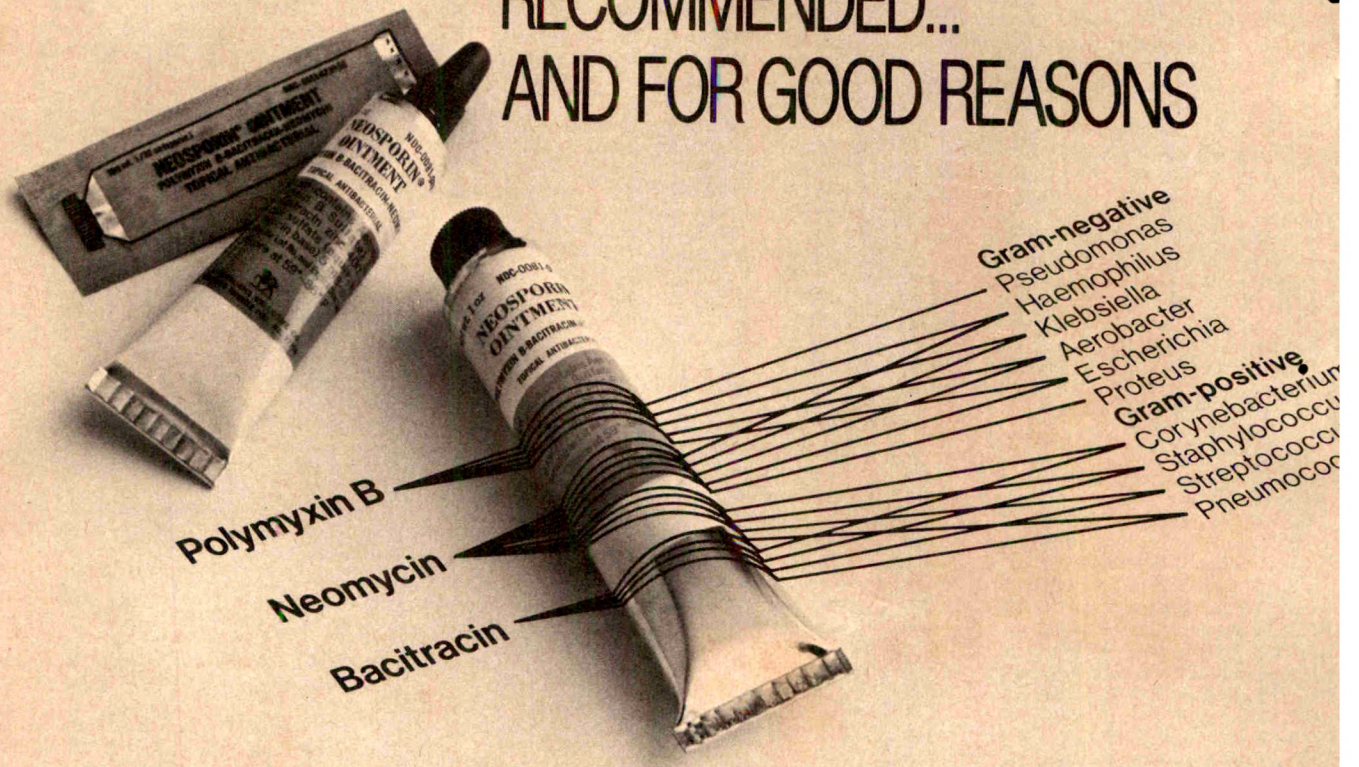
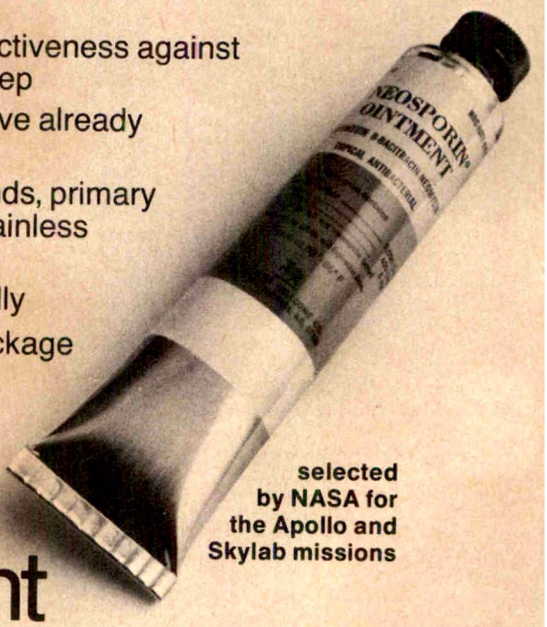
IT'S HIGHLY RECOMMENDED... AND FOR GOOD REASONS



1. provides broad-spectrum, overlapping antibacterial effectiveness against common susceptible pathogens, including staph and strep
2. helps prevent topical infections, and treats those that have already started
3. it's good medicine for abrasions, lacerations, open wounds, primary pyodermas, secondarily infected dermatoses; and it's painless and cosmetically pleasing
4. contains three antibiotics that are rarely used systemically
5. you can recommend it in any of the three convenient package sizes: 1 oz tube, ½ oz tube, or the versatile, single-use foil packet



selected by NASA for the Apollo and Skylab missions

NEOSPORIN® Ointment

(polymyxin B-bacitracin-neomycin)

Each gram contains: Aerosporin® (Polymyxin B Sulfate) 5,000 units, bacitracin zinc 400 units, neomycin sulfate 5 mg (equivalent to 3.5 mg neomycin base); special white petrolatum qs; in tubes of 1 oz and 1/2 oz and 1/32 oz (approx.) foil packets.

WARNING: Because of the potential hazard of nephrotoxicity and ototoxicity due to neomycin, care should be exercised when using this product in treating extensive burns, trophic ulceration and other extensive conditions where absorption of neomycin is possible. In burns where more than 20 percent of the body surface is affected, especially if the patient has impaired renal function or is receiving other aminoglycoside antibiotics concurrently, not more than one application a day is recommended.

When using neomycin-containing products to control secondary infection in the chronic dermatoses, it should be borne in mind that the skin is more liable to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as a failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.

PRECAUTIONS: As with other antibacterial preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

ADVERSE REACTIONS: Neomycin is a not uncommon cutaneous sensitizer. Articles in the current literature indicate an increase in the prevalence of persons allergic to neomycin. Ototoxicity and nephrotoxicity have been reported (see Warning section).

ONE HUNDRED YEARS WELLCOME

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709

Radiological Case of the Month

Lionel W. Young, MD;

Contributed by James W. Lowell, MD, Bertram R. Girdany, MD

This 5-year-old girl was referred to an orthopedic surgeon because of pain in her left wrist for a period of weeks. Three months previously, she had hurt the dorsum of her left hand and wrist in a fall. The lateral aspect of the dorsum of the hand was swollen. A roentgenogram of the left hand was obtained (Fig 1 and 2). A chest roentgenogram was normal. Skin tests for microbacterial and fungal causes were negative. A complete blood cell count was normal. The carpal lesion underwent biopsy and was partially resected.

From the Department of Radiology (Dr Lowell), St Joseph Mercy Hospital, Pontiac, Mich; and the Department of Radiology (Dr Girdany), Children's Hospital of Pittsburgh.

Reprint requests to Department of Radiology, Children's Hospital of Pittsburgh, 125 DeSoto St, Pittsburgh, PA 15213 (Dr Young).

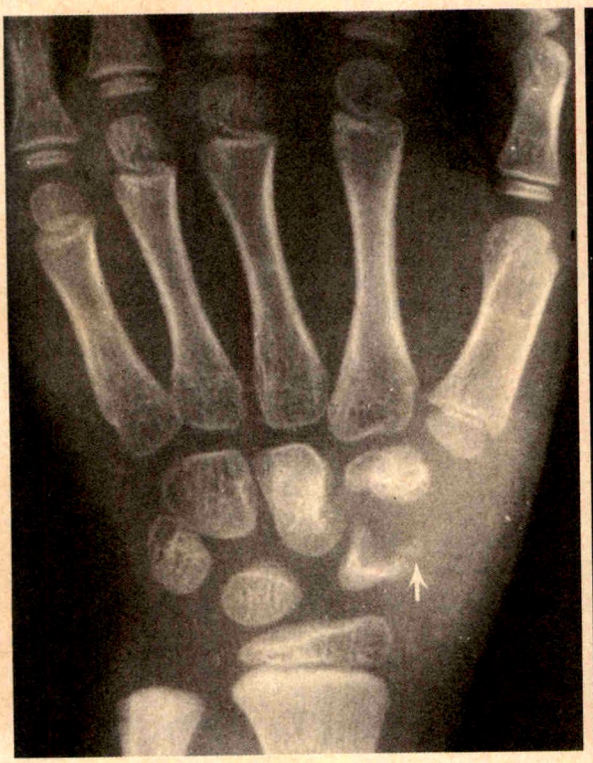

Figure 1.

Figure 2.

Denouement and Discussion

Fig 1.—Anteroposterior view of left wrist. There is erosive bone destruction of most of navicula, lateral margin of capitate, and proximal margin of lesser multiangular area. Note calcification (arrow) adjacent to navicula and surrounding soft-tissue swelling.

Fig 2.—Lateral view of left wrist. Note erosion of lesser multiangular area (arrowhead) and soft-tissue swelling.

Fig 3.—Microscopic section in low-power magnification (hematoxylin-eosin, ×90). See first paragraph of "Discussion."

Fig 4.—Microscopic section in high-power magnification (hematoxylin-eosin, ×500). See first paragraph of "Discussion."

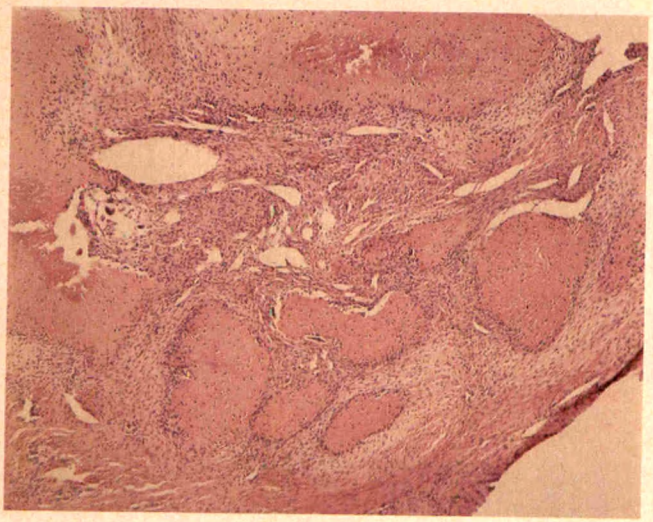

Figure 3.

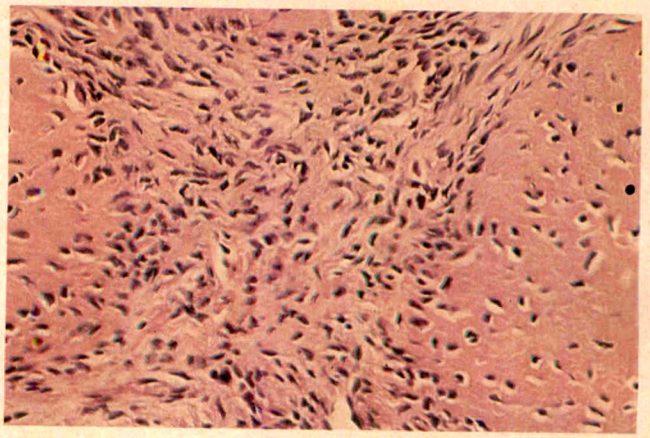

Figure 4.

Juvenile Aponeurotic Fibroma

Microscopic examination of sections of the lesion (Fig 3 and 4) showed degenerating focally hyalinized fibrocartilagenous tissue and fragments of proliferating fibroblastic cells arranged in nodules, palisading or intertwining tangles of eosinophilic spindle-shaped cells. Nuclei were oval or spindle shaped, moderately hyperchromatic, and uniform in size. Several islands of cartilagenous metaplasia with focal calcification were present within an area of neoplastic cell proliferation, but there was no evidence of malignancy. The findings were diagnostic of juvenile aponeurotic fibroma (JAF).

Juvenile aponeurotic fibroma is a rare, benign neoplasm of the fascia, aponeuroses, and muscles, usually of the hands and wrists or feet and ankles of children and adolescents.[1-3] It is more common in boys, but does not follow a definite history of trauma. The mass may be circumscribed or diffuse and is usually painless.[4] Although JAF is infiltrative and infrequently recurrent, malignant degeneration has not been reported.[5] The lesion may be grouped with other relatively nonaggressive fibromatoses among which are congenital generalized fibromatosis, fibromatosis colli, fibrous hamartoma of infancy, recurring digital fibrous tumor of Reye, juvenile hyaline fibromatosis, diffuse infantile fibromatosis, and hereditary gingival fibromatosis.[6]

Roentgenographically, JAF appears as a soft-tissue mass that may be stippled with calcium and that erodes adjacent bone (Fig 1 and 2). The differential diagnosis includes giant-cell tumor of the tendon sheath, fibrous lymphoma of the tendon sheath, soft-tissue chondroma, periosteal chondroma, and synovial sarcoma.[6]

This neoplasm is composed of dense cellular fibrous tissue that infiltrates fat, muscles, collagen bundles, nerves, and adjacent bones, and it is unencapsulated.[4,7-9] It may be distinguished from other fibromatoses by focal chondroid differentiation within a proliferation of spindle cells. Palisading calcifications occur within the lesion.

In spite of frequent recurrences, management of JAF has been conservative because of the unlikelihood of malignant degeneration. In follow-up of this girl during a three-year period, she has had no pain, tenderness, or swelling of the wrist after partial resection of the lesion.

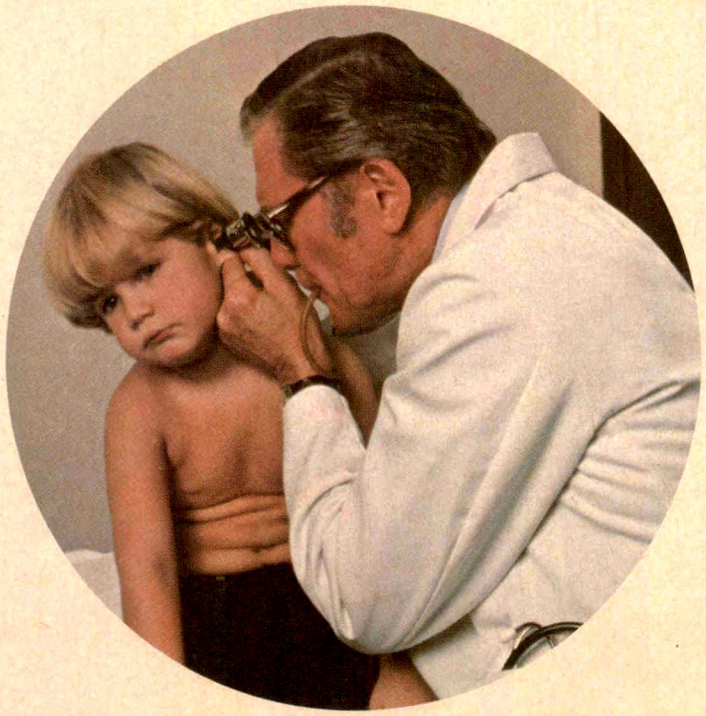
Ceclor®
cefaclor

A newly developed oral antibiotic useful in acute otitis media*



A newly developed oral antibiotic

Ceclor® cefaclor

Consider the changing bacterial

Increasing incidence of otitis media caused by H. influenzae

Reports from many areas of the country show that the bacterial pattern seen in otitis media is changing. Published studies suggest that the incidence of otitis media caused by *H. influenzae* is increasing.[1,2]

In fact, the American Academy of Pediatrics' Committee on Infectious Diseases reports that relapses of otitis media have been more common with *H. influenzae* than with other organisms.[3]

H. influenzae resistance is a growing problem

Percentage of Ampicillin-Resistant *H. influenzae* Isolates*

	1975	1976	1977
Boston[4]	5.3%	10.2%	15.6%
Fresno[5]	—	—	4.8
Huntsville[4]	1.4	2.8	13.6
Washington, D.C.[6]	1.6	18	35
Oklahoma City[7]	—	—	22

*Isolates obtained from a variety of body fluids (middle-ear exudate, blood, etc.).

Recommendations regarding treatment of otitis media caused by H. influenzae

The American Academy of Pediatrics, in its recommendations for the treatment of otitis media, reports that *H. influenzae* is often the suspected pathogen in children less than eight years of age. They further report that ampicillin-resistant strains of *H. influenzae* have been isolated. The physician should therefore consider ampicillin resistance in the child with acute otitis media, particularly one who does not show clinical improvement after 48 to 72 hours of ampicillin therapy.[8]

Investigators have suggested a need for alternative antimicrobials in the treatment of otitis media caused by ampicillin-resistant *H. influenzae*.[9,10]

Ceclor® (cefaclor) is effective in the treatment of acute otitis media due to susceptible strains of these microorganisms:

- *S. pneumoniae*
- *H. influenzae* (including beta-lactamase-producing ampicillin-resistant strains)
- Staphylococci (including coagulase-positive, coagulase-negative, and penicillinase-producing strains)
- *S. pyogenes* (group A beta-hemolytic streptococci)

In studies of 246 patients with otitis media, Ceclor demonstrated a 93 percent clinical and bacteriologic success rate (see accompanying chart).[11]

Clinical and Bacteriologic Responses by Pathogen in 246 Infants and Children with Otitis Media[11]

		Satisfactory Responses	
Pathogen	Number of Patients	Clinical (Symptomatic)	Bacteriologic
S. pneumoniae	127	121	121
S. pyogenes	11	11	11
Staphylococcus aureus	21	18	19
H. influenzae	74	67	66
Multiple organisms	13	12	12
Totals	246	229 (93%)	229 (93%)

See the following page for criteria for diagnosis and response.

pattern of acute otitis media*

Good taste and t i d administration may aid patient compliance

Ceclor may be administered t i d. The pleasant-tasting oral suspensions encourage patient cooperation:

125 mg/5 ml, strawberry flavor
250 mg/5 ml, grape flavor

Criteria for diagnosis and response

Diagnosis:
Diagnosis of otitis media was confirmed in all patients by culture of middle-ear aspirate or exudate within 24 hours after the start of therapy. Exudate was acceptable as a culture source for only pneumococci, *H. influenzae*, and group A streptococci. Additional specimens for culture were obtained during and after therapy as deemed necessary by the clinician. The bacteriologic response was based on results during the ten to 16-day posttherapy follow-up period.

Clinical (symptomatic) response:
Satisfactory = disappearance of or improvement in signs and symptoms of the principal infection, with or without recurrence of signs or symptoms during the posttherapy follow-up period.

Unsatisfactory = no improvement in signs and symptoms at the end of therapy.

Bacteriologic response:
Cure = pathogen(s) eliminated or reduced to insignificant numbers during therapy or elimination of the original pathogen during therapy, followed by a culture positive for a new pathogen (reinfection) either during therapy or during the posttherapy follow-up period.

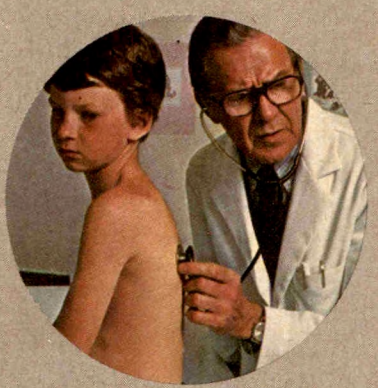
Failure = failure of the treatment to eradicate the pathogen(s) or initial eradication of the pathogen(s), followed by relapse with the same pathogen during therapy or during the posttherapy follow-up period.

Ceclor is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

*Due to susceptible strains of *S. pneumoniae*, *H. influenzae*, staphylococci, and *S. pyogenes*.

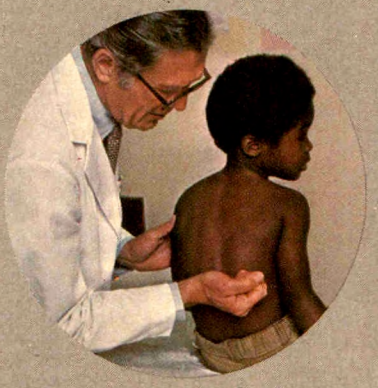
Ceclor® (cefaclor) is also indicated for these other common infections

Clinical trials have demonstrated the effectiveness of Ceclor against the following common infections when caused by susceptible strains of the designated microorganisms:



Lower respiratory infections
including pneumonia caused by *S. pneumoniae*, *H. influenzae*, and *S. pyogenes* (group A beta-hemolytic streptococci)

Upper respiratory infections
including pharyngitis and tonsillitis caused by *S. pyogenes* (group A beta-hemolytic streptococci)



Urinary tract infections
including pyelonephritis and cystitis caused by *Escherichia coli*, *Proteus mirabilis*, *Klebsiella* species, and coagulase-negative staphylococci

Skin and skin-structure infections
caused by *S. aureus* and *S. pyogenes* (group A beta-hemolytic streptococci)

Note: Penicillin is the usual drug of choice in the treatment and prevention of streptococcal infections, including the prophylaxis of rheumatic fever. See summary of prescribing information.

See the following page for summary of prescribing information.

000099

A newly developed oral antibiotic

Ceclor® cefaclor

Pediatric Dosage			
Mild to Moderate Infections (20 mg/kg/day)			
125 mg (½ tsp t i d)	**125 mg** (1 tsp t i d)	**250 mg** (1 tsp t i d)	
0-20 lb 0-9 kg	20-40 lb 9-18 kg	40-55 lb 18-25 kg	
More Serious Infections and Otitis Media* (40 mg/kg/day)			
125 mg (½ tsp t i d)	**125 mg** (1 tsp t i d)	**250 mg** (1 tsp t i d)	**250 mg** (1 gm in 3 divided doses)
0-10 lb 0-4.5 kg	10-20 lb 4.5-9 kg	20-40 lb 9-18 kg	40-55 lb 18-25 kg

125 mg, Strawberry 250 mg, Grape

The usual recommended daily dosage for children is 20 mg/kg/day in divided doses every eight hours.

In more serious infections, otitis media,* and infections caused by less susceptible organisms, 40 mg/kg/day are recommended, with a maximum dosage of 1 gm per day.

Safety for use in infants less than one month of age has not been established.

*Due to susceptible strains of *S. pneumoniae, H. influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci).

Ceclor® (cefaclor)

Brief Summary. Consult the package literature for prescribing information.

Indications and Usage: Ceclor is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms:

Otitis media caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci)

Lower respiratory infections, including pneumonia caused by *S. pneumoniae (D. pneumoniae), H. influenzae,* and *S. pyogenes* (group A beta-hemolytic streptococci)

Upper respiratory infections, including pharyngitis and tonsillitis caused by *S. pyogenes* (group A beta-hemolytic streptococci)

Note: Penicillin is the usual drug of choice in the treatment and prevention of streptococcal infections, including the prophylaxis of rheumatic fever. Cefaclor is generally effective in the eradication of streptococci from the nasopharynx; however, substantial data establishing the efficacy of cefaclor in the subsequent prevention of rheumatic fever are not available at present.

Urinary tract infections, including pyelonephritis and cystitis caused by *Escherichia coli, Proteus mirabilis, Klebsiella* species, and coagulase-negative staphylococci

Skin and skin-structure infections caused by *Staphylococcus aureus* and *S. pyogenes* (group A beta-hemolytic streptococci)

Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor.

Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PENICILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS TO BOTH DRUG CLASSES (INCLUDING ANAPHYLAXIS AFTER PARENTERAL USE).

Antibiotics, including Ceclor® (cefaclor, Lilly), should be administered cautiously to any patient who has demonstrated some form of allergy, particularly to drugs.

Precautions: If an allergic reaction to cefaclor occurs, the drug should be discontinued, and, if necessary, the patient should be treated with appropriate agents, e.g., pressor amines, antihistamines, or corticosteroids.

Prolonged use of cefaclor may result in the overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Positive direct Coombs tests have been reported during treatment with the cephalosporin antibiotics. In hematologic studies or in transfusion cross-matching procedures when antiglobulin tests are performed on the minor side or in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it should be recognized that a positive Coombs test may be due to the drug.

Ceclor should be administered with caution in the presence of markedly impaired renal function. Under such a condition, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended.

Usage in Pregnancy—Although no teratogenic or antifertility effects were seen in reproduction studies in mice and rats receiving up to 12 times the maximum human dose or in ferrets given three times the maximum human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

Usage in Infancy—Safety of this product for use in infants less than one month of age has not been established.

Adverse Reactions: In clinical studies in 1493 patients, adverse effects considered related to cefaclor therapy were uncommon and are listed below:

Gastrointestinal symptoms occurred in about 2.5 percent of patients and included diarrhea (1 in 70) and nausea and vomiting (1 in 90).

Hypersensitivity reactions were reported in about 1.5 percent of patients and included morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs tests each occurred in less than 1 in 200 patients.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain—Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic—Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic—Transient fluctuations in leukocyte count, predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal—Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

Administration and Dosage:

Ceclor® (cefaclor, Lilly) is administered orally.

Adults—The usual adult dosage is 250 mg every eight hours. For more severe infections (such as pneumonia) or those caused by less susceptible organisms, doses may be doubled. Doses of 4 gm per day have been administered safely to normal subjects for 28 days, but the total daily dosage should not exceed this amount.

Children—The usual recommended daily dosage for children is 20 mg/kg/day in divided doses every eight hours, as indicated:

Child's Weight	Ceclor Suspension 125 mg/5 ml	Ceclor Suspension 250 mg/5 ml
9 kg	1/2 tsp t i d	
18 kg	1 tsp t i d	1/2 tsp t i d

In more serious infections, otitis media, and infections caused by less susceptible organisms, 40 mg/kg/day are recommended, with a maximum dosage of 1 gm per day.

Ceclor may be administered in the presence of impaired renal function. Under such a condition, the dosage usually is unchanged (see Precautions).

In the treatment of beta-hemolytic streptococcal infections, a therapeutic dosage of Ceclor should be administered for at least ten days. [070379]

Spontaneous Splenic Rupture in Acute Lymphoblastic Leukemia: Successful Nonoperative Management

Spontaneous rupture of the spleen is a rare complication in patients with acute leukemia.[1-8] In most of the patients diagnosis has been made postmortem, though successful removal of the spleen has been accomplished in a few. Recently, we encountered a case of acute T-cell leukemia in which intraperitoneal bleeding and shock were due to splenic rupture. The patient's condition was managed successfully without surgical intervention.

Report of a Case.—A 13-year-old boy was admitted to Children's Hospital of Michigan, Detroit, on June 14, 1978, with a two-week history of mild difficulty in breathing, generalized petechiae, prominent bilateral cervical adenopathy, and hepatomegaly (5 cm) and splenomegaly (7 cm). The following laboratory values were reported: hemoglobin, 14.2 g/dL; WBCs, 174,000/cu mm, with 90% lymphoblasts; and platelets, 28,000/cu mm. Chest roentgenogram showed an enlarged thymus. Bone marrow examination confirmed the diagnosis of acute lymphoblastic leukemia, and the leukemic blasts formed spontaneous rosettes with sheep erythrocytes, indicating the T-cell nature of the blast cells. The uric acid value was 24 mg/dL, and the BUN level was 24 mg/dL.

Initial treatment was aimed at prevention of serious bleeding complications and uric acid nephropathy. Pooled platelet transfusion (10 units) was given on the day of admission and again the next evening. A single course of radiotherapy (50 rads) was given to the neck and upper part of the chest on the second hospital day to relieve the respiratory difficulty. Vigorous alkalinization of the urine and allopurinol administration resulted in a reduction of the uric acid level to 9.6 mg/dL and the BUN value to 11.5 mg/dL on the fifth hospital day. Other laboratory values were as follow: hemoglobin, 10.7 g/dL; hematocrit, 34%; WBCs, 93,000/cu mm; and platelets, 9,000/cu mm. Arrangements for platelet transfusions were made and start of chemotherapy planned.

However, he suddenly complained of severe pain in the left shoulder and left side of the chest and became restless. Physical examination showed no abnormalities. The pain and restlessness subsided spontaneously within a few minutes, but the patient felt weak. Approximately two hours later, he was found to be extremely pale, incoherent, and in shock. Pulse rate was 126 beats per minute; blood pressure (BP) 90/70 mm Hg; and respiratory rate, 34/min. The abdomen was soft and there was tenderness in the left upper quadrant. The previously enlarged spleen was now difficult to palpate. Bowel sounds were normal.

There was no history of trauma and no obvious evidence of blood loss such as hematemesis, melena, or rectal bleeding. The patient was immediately given 1,050 mL of packed RBCs (PRBCs) and 10 units of pooled platelets, along with normal saline solution and hydrocortisone sodium succinate, 150 mg every six hours. With these measures, the BP rapidly increased to 120/60 mm Hg, and the patient became oriented and alert.

The abdomen, however, was noted to be distended, with tenderness in the epigastrium and shifting dullness. In spite of the large volume of blood transfused, the hemoglobin level was 9.9 g/dL. A possible splenic rupture was suspected, and a plain film of the abdomen showed intraperitoneal fluid.

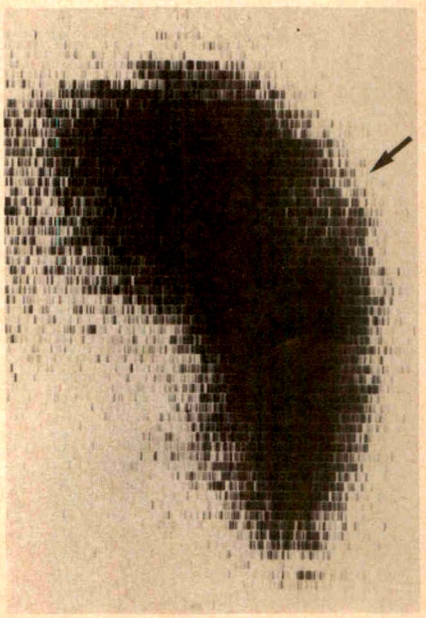
During the next 24 hours, transfusion of 2,000 mL of whole blood and platelet transfusions 12 hours apart were necessary to maintain a hemoglobin level of more than 10 g/dL and normal BP. Subsequently, platelet transfusions were given twice daily. This apparently controlled the bleeding as he required the transfusion of PRBCs only once more.

Hydrocortisone administration was continued and remission induction was begun with vincristine sulfate therapy on the seventh hospital day. This was followed by a rapid increase in the BUN level to 134 mg/dL, necessitating hemodialysis daily for five days. By the 15th hospital day, the patient's overall condition stabilized, the platelet counts began to increase, and the platelet transfusions were discontinued. Sodium pertechnetate Tc 99m spleen scan performed two weeks after the episode of shock showed a cold spot in the left upper pole, thus confirming a splenic hematoma or rupture (Figure).

The patient subsequently completed the initial induction chemotherapy and was in hematologic remission by Aug 4, 1978. Initial remission lasted six months, and the patient died in refractory relapse on July 2, 1979.

Comment.—Considering the vascularity of the spleen, its lack of supportive tissue, and the thin splenic capsule, it is surprising to find that spontaneous rupture of the spleen is a rare occurrence in acute leukemia. Thus far, only 19 cases of spontaneous splenic rupture in acute leukemia have been reported.[1,3,5-8] The acute leukemia was of the lymphoid type in nine, and only one patient was in the pediatric age group.[3]

In our patient, the intraperitoneal bleeding most likely occurred from a subcapsular infarction of the spleen, with subsequent tear through the capsule. The infarction probably occurred



Sodium pertechnetate Tc 99m scan of spleen showing area of decreased uptake (arrow) in upper part of spleen.

at the time the patient experienced severe left shoulder and left lower chest pain. Such symptoms occurred in almost all of the previously reported cases, with the onset of shock delayed, as in our patient, by a few hours to several days. Our experience suggests that, rare as it may be, splenic infarction should be suspected in any leukemic patient with similar findings and that such patients should be monitored closely for signs of impending shock. A splenic scan may be a valuable aid in the final diagnosis.

Splenectomy for rupture of the spleen has been the standard mode of therapy until now. In recent years, owing to the realization of susceptibility to overwhelming infection in splenectomized individuals, splenorrhaphy and nonoperative management of splenic rupture are becoming more common.[9-11] Howman-Giles et al[10] recommended nonoperative management in selected children with traumatic rupture of the spleen who are clinically stable or can be maintained in a stable condition with intravenous fluids or blood.

The management of splenic rupture in a leukemic patient in relapse poses special problems because of the thrombocytopenia and susceptibility to infections. In our case, vigorous treatment with repeated platelet transfusions and PRBC transfusions stabilized his condition and controlled the bleeding, and the subsequent complete recovery negated the need for splenectomy.

In retrospect, this case illustrates that nonoperative management of splenic rupture can be successful even in thrombocytopenic patients. This method of treatment should be considered in all patients with splenic rupture unless the patient's condition cannot be stabilized. To our knowledge, this is the first reported example of successful nonoperative management of spontaneous rupture of the spleen in a leukemic patient.

Doxepin Poisoning in a Child

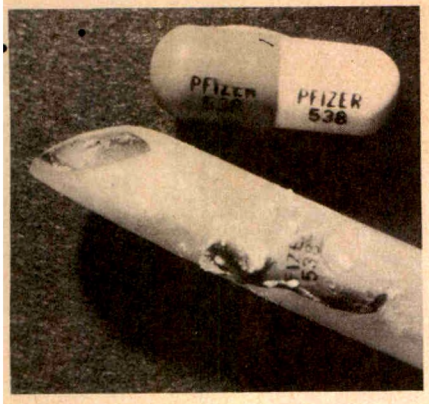
Tricyclic antidepressant drug overdose is an increasingly frequent cause of serious poisoning.[1] Imipramine and amitriptyline poisonings have been more commonly reported,[2-4] whereas the toxicity of doxepin, a newer drug of this class, is less well described.[5] We present a case of severe doxepin hydrochloride poisoning in a child who survived and in whom the diagnosis was made in an unusual and unexpected manner. To our knowledge, no case of doxepin poisoning in a child has been previously reported.

Report of a Case.—A 4-year, 6-month-old, 13-kg girl collapsed for no apparent reason after a morning of normal activity and was taken comatose to her local physician. A grand mal seizure ensued that progressed to status epilepticus during her transfer to the University of Kansas Hospital, Kansas City. The history obtained from the parents was negative for metabolic or seizure disorders. The parents did not suspect any drug or toxic chemical ingestion. On arrival at the hospital two hours after onset of her symptoms, the child was unresponsive to pain; her pupils were equally dilated and unreactive to light. She was having continuous seizures consisting of rapid twitching of the eyelids and extremities. Clinical observations were as follows: systolic blood pressure, 60 torr; respirations, 10/min and shallow; heart rate, variable at approximately 120 beats per minute; and rectal temperature, 36 °C.

Because of inadequate respiratory effort, the patient was intubated and given mechanical ventilatory assistance. Seizure activity persisted after administration of 10 mg of diazepam intravenously, but it was controlled with 100 mg of intravenous (IV) phenobarbital sodium. There was no improvement in the patient's condition after IV administration of naloxone hydrochloride, 0.06 mg, and 2.5 g of dextrose. Metabolic acidosis (pH, 7.27) and hypotension were rapidly corrected with adequate ventilation and appropriate IV fluids. Gastric lavage followed by intragastric instillation of activated charcoal was performed. The gastric contents had a bluish discoloration, but they contained no identifiable capsules or tablets. The child was given magnesium citrate three hours after the activated charcoal, but she did not have a stool. Bowel sounds ranged from decreased to absent.

During the initial intubation, a portion of a blue capsule was retrieved from the esophagus (Figure). The product identification number was legible, which allowed identification of the drug as doxepin (Sinequan), 100 mg. Thin-layer chromatography of an extract of the patient's urine verified the presence of unmetabolized doxepin and was negative for other drugs. When confronted with this information, the parents acknowledged having doxepin at home and later found 32 doxepin capsules along with 15 pentazocine hydrochloride tablets in a bottle under the patient's bed. The original quantities of each drug were unknown.

Based on the capsule identification, the patient was given physostigmine salicylate (1.5 mg) intravenously in three divided doses five minutes apart. Respiratory effort increased substantially, and her pupils became reactive to light; no other effects were observed. The body temperature remained below normal for the first five hours after admission, but then it became elevated for the next 24 hours. The child's respiratory effort and responsiveness to external stimuli improved during the second 12 hours of hospitalization, and she was extubated 20 hours after admission. She remained lethargic but responded to verbal stimuli and seemed to recognize her parents. Some 24 hours after admission, the patient was given two additional doses of physostigmine salicylate, 0.5 mg



Tip of endotracheal tube with adherent foreign material after attempted intubation. Capsule of doxepin (Sinequan) from patient's pill collection is shown for comparison.

each, after which she became much more alert, began talking, and passed a large charcoal stool.

The child's condition was evaluated by a cardiac monitor for the first five days of hospitalization, and no arrhythmias were detected at any time. The EEG and ECG were normal one week after admission. The patient remained ataxic for two days after admission, but this resolved and her neurologic examination showed no abnormalities ten days after the onset of symptoms.

Comment.—Ingestion of a toxin must always be included in the differential diagnosis of status epilepticus and coma in children. When the cause of the symptoms is not readily apparent, gastric lavage along with measures to inhibit further gastrointestinal (GI) absorption of a potential poison are mandatory parts of the emergency protocol. Pharmacologic screening of the urine or serum should also be a part of the evaluation of the patient. The drug imprint code on capsules or tablets, when available, can be an invaluable aid in arriving at a diagnosis. The present case dramatically illustrates these points.

Although this child had access to pentazocine in addition to doxepin, the clinical manifestations were most consistent with doxepin toxicity. The absence of pentazocine in the urine and the lack of effect by naloxone on respiration or level of consciousness also ruled out pentazocine ingestion. Respiratory depression, coma, and grand mal seizures are well-documented symptoms of a tricyclic antidepressant toxic condition. Hypotension, hyperthermia (which followed initial hypothermia), and dilated pupils are also characteristic.[2-4] In spite of these severe symptoms, the ECG of our patient, monitored continuously for five days, showed no evidence of cardiac arrhythmias or conduction abnormalities, which are frequently seen in tricyclic antidepressant overdose. This is consistent with the previously reported observation that although other tricyclic antidepressants alter intraventricular conduction, doxepin does not share this effect.[4,5]

Physostigmine has emerged as the cholinesterase inhibitor of choice in the treatment of life-threatening symptoms caused by the anticholinergic actions of the tricyclic antidepressants.[1,3,5,6] We observed a definite clinical improvement in this patient after administration of moderate doses of physostigmine salicylate (0.5 mg thrice, and later, 0.5 mg twice). Some authors have reported more aggressive use of physostigmine in cases of tricyclic antidepressant intoxication than was used for our patient; however, she recovered rapidly and completely with supportive care and cautious use of physostigmine.

Tricyclic antidepressants and their active metabolites undergo enterohepatic recycling and gastric secretion. Therefore, the administration of activated charcoal may speed the elimination of these compounds from the body.[1] In this patient, magnesium was ineffective in stimulating the movement of charcoal and adsorbed drug through the GI tract until physostigmine was administered. This complication of anticholinergic intoxication should be kept in mind when managing the conditions of such patients.

Recordkeeping and Physician Certification of Measles Immunization Status

The recent federally sponsored objective of achieving immunization levels of at least 90% in US children by 1979[1] is predicated on the assumption that all links in the chain of immunization recordkeeping are appropriately maintained, honestly evaluated, and fully reported. I report here an epidemic that demonstrates how these records can break down at two levels of reporting: the physician's office and the school.

Report of a Case. In February 1978, the Livingston County Health Department, Howell, Mich, received a school-initiated report that an open classroom elementary school with an enrollment of 512 students had eight cases of measles. The index case, an 8-year-old second-grader, was identified. We were unable to determine the index case's initial exposure; however, the potential for exposure was high as during this time in Michigan there were numerous outbreaks of measles in different communities around the state, including a large outbreak at one of the state's major universities in a county adjoining Livingston County.

This school had reported nearly perfect (99%) immunization compliance status for its entering children during the past two to three years. At the time, state law did not specify the minimum age for measles immunization.

In attempting to contain this outbreak, we reviewed the school immunization records of all 512 pupils to locate potentially susceptible children: those students who were not previously vaccinated or who were vaccinated at less than 13 months of age. The intent of the review was to notify only parents of susceptible children.

The results of our measles immunization status review of the 512 children were as follow:

1. Readily determined immunization information was available (*a*) for 24 (4.7%) children vaccinated before or at 12 months of age, (*b*) for 122 (23.8%) children vaccinated after 12 months of age, and (*c*) for 18 (3.5%) children not vaccinated.

2. No immunization records were pres-

ent in 81 (15.8%) children's school files, *or* the records were not completed.

3. Dates of measles immunizations in vaccination records were indeterminable for 255 (49.8%). (This includes two records marked "complete"; nine, "adequate"; and three, "up-to-date." Subsequent study showed that of the 348 students with incomplete, inaccurate, or nonexistent records, there were 138 who had not been adequately vaccinated.)

4. The students' files were not found for 12 (2.3%).

As is evident from this information, we were unable to determine the adequacy of immunization of 68.0% of the children. Hence, notes were sent to all children's homes requesting parents to reevaluate their children's measles vaccine status.

After the epidemic in the fall of 1978, a record review for all state-required immunizations was performed. Parents were contacted and asked to supply us with the month and year of measles immunization. After this contact, we found that an additional 210 of the children had been in compliance at the time of the outbreak, leaving 138 children inadequately immunized.

Comment.—To enhance the effectiveness and efficiency of communicable disease outbreak containment in institutional environments, complete and accurate records are a must. Because in this situation the records were difficult to interpret, we were forced to notify the entire population—an inefficient modus operandi.

The deficiencies in these school records were in four areas: (1) the school, which neither demanded the month and year of immunization nor excluded the noncompliant pupil; (2) the physician, who did not give the parents written records of their child's immunization history, who did not emphasize the necessity for the parent to keep the record permanently in good repair, or who supplied inadequate information on the written record; (3) the parent, who did not present the full information to the school when requested; and (4) the health department, which has not previously stringently enforced the school-entering law, thus assuring that a child's *reported* compliance is the *actual* immunization status of that child.

On at least two occasions when physicians who stamped "immunizations complete" or "immunizations adequate" on the school forms were contacted, we found that the children had not received measles immunization, a finding that has profound health and legal implications.

As in other areas of medicine, immunization standards of care are frequently changing, requiring precise medical histories for frequent reevaluation of vaccination status. The importance of age at vaccination for measles is just now being clarified. For many years, it was assumed that vaccination at age 12 months offered adequate protection, but recent studies showed that age-specific attack rates were substantially higher in those vaccinated before age 12 months.[2-6]

The debate on the necessity for revaccination of those children initially vaccinated prior to 13 months continues.[5-7] When, and if, this debate is resolved, physicians will have to work with the schools to assure the adequacy of our children's protection against vaccine-preventable disease. Without accurate records, this assurance is impossible. Furthermore, schools will be unable to comply with changing immunization rules and regulations if their current records are not complete.

The inadequacy of immunization care is not unique to private practitioners in a relatively rural area like Livingston County. Pope[8] has demonstrated less-than-optimal immunization standards in a health maintenance organization population, where he found that 12% of eligible children had not been vaccinated against measles. Moreover, about 50% of all school-age children cared for by this particular organization had not received one or more of the school-required immunizations.

Through complete physician cooperation, we can all help our patients meet the objectives of the national immunization initiative. Rigorous attention to immunization records can help to avoid large outbreaks of vaccine-preventable disease.

Symptomatic Hyponatremia in Nephrotic Syndrome

Hyponatremia may occur in children with nephrotic syndrome, usually when diuretic therapy has been used. Hyponatremia owing to inadequate salt intake, in the absence of diuretic treatment, is an unusual but probably overlooked cause.[1,2] We report our experience in caring for a 2½-year-old boy with steroid-responsive nephrotic syndrome who had disorientation and hallucinations as a result of severe hyponatremia.

Report of a Case.—A male infant had classical nephrotic syndrome at age 21 months. He responded within two weeks to oral prednisone (2 mg/kg/day), with resolution of the edema and disappearance of the proteinuria. The prednisone dose was reduced during the next several weeks until a clinical relapse occurred. Again, daily prednisone treatment induced a remission, and a course of alternate-day prednisone was planned. While taking 40 mg of prednisone every other day, he had proteinuria (4+) without edema and, four days later, the prednisone dosage was increased to 10 mg four times daily. No diuretic therapy was given. His weight was 17.3 kg and he did not appear swollen.

Five days later, he had edema and complained of abdominal discomfort. He had no fever, emesis, or diarrhea but was not eating well. The abdominal examination was consistent with moderate ascites; there were no signs of peritonitis. His weight was 19.5 kg, and he was alert and cooperative and was not in any distress. Vital signs, including blood pressure and temperature, were normal. He was admitted to the hospital for observation of possi-

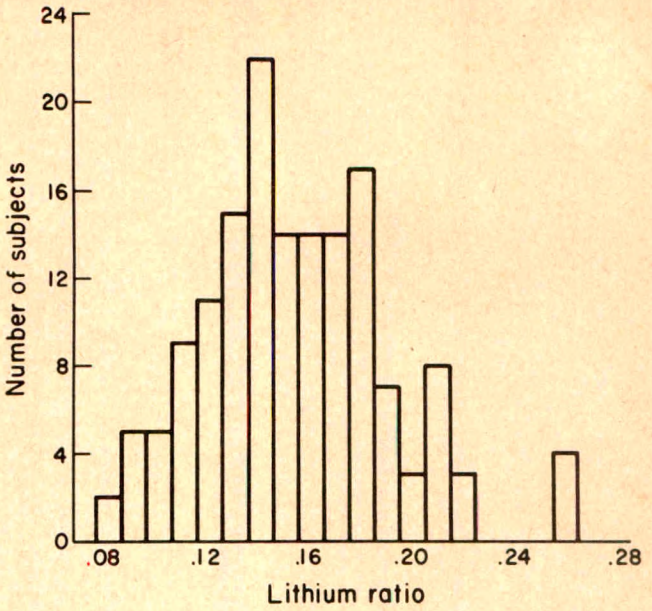
ble early peritonitis.

Laboratory studies showed the following values: initial serum electrolyte, severe hyponatremia (see Table); BUN, 38 mg/dL; creatinine, 0.7 mg/dL; albumin, 1.9 g/dL; and cholesterol, 602 mg/dL. Serum Na was repeated six hours later (110 mEq/L), and the laboratory reported that his serum was not visibly lipemic. He remained alert with normal vital signs but because of the severity of the hyponatremia, an intravenous (IV) infusion of 0.9% sodium chloride solution was begun at a rate of 40 mL/kg/day. He was not permitted oral fluids. Fifteen hours later, the serum concentrations were as follow: Na, 98 mEq/L; Cl, 77 mEq/L; K, 5.8 mEq/L; and osmolality, 241 mOsm/L. Simultaneously, he had become extremely agitated and was exhibiting inappropriate behavior (biting mother and staff) as well as hallucinating about the presence of bugs and insects on the walls of his room. There was no seizure activity and vital signs were normal.

Hypertonic (3%) saline solution was administered; 24 hours later, his serum Na value was 127 mEq/L, and he again was oriented. As a result of the IV fluids, a further increase in edema occurred and furosemide therapy was begun on the third hospital day. After 20 days of daily prednisone therapy, he again had a clinical remission (weight decreased to 17.3 kg, no proteinuria). Serum electrolyte values were as follow: Na, 140 mEq/L; K, 4.4 mEq/L; Cl, 104 mEq/L; and CO_2, 24 mEq/L.

Dietary history indicated that the patient's mother had kept him on a severely restricted salt diet continuously since the initial diagnosis of his condition. The diet consisted of no salty foods and no salt with cooking, as well as low-salt bread, ketchup, margarine, etc.

Comment.—Nephrotic syndrome is usually an easily recognizable condition characterized by edema, proteinuria (> 50 mg/kg/day), hyperlipidemia, and hypoalbuminemia. In the untreated state (ie, no diuretics), serum Na concentration is most often normal and osmolality is normal to slightly elevated. "Pseudohyponatremia" may occur when the elevated serum lipids decrease the serum water content. In this instance, serum is visibly lipemic and serum osmolality, the measurement of which is unaffected by lipidemia, is not decreased.[3] In our patient, the serum osmolality was decreased, and although the serum cholesterol level was 602 mg/dL, the serum did not appear lipemic. Furthermore, no vomiting or diarrhea had occurred to account for an external loss of Na. The urinary Na concentration was negligible, indicating an appropriate Na-retaining state and thus not suggesting aldosterone deficiency, syndrome of inappropriate secretion of antidiuretic hormone, or salt-losing renal disease as explanations for this hyponatremia. Hyperglycemia is another cause of hyponatremia,[4] but there was no evidence for this in our patient.



The most reasonable explanation for this youngster's hyponatremia is a deficiency of dietary salt combined with the dilutional effect of his 2.3-kg gain in body water. The reason for the continued decrease in serum Na while he was receiving a small amount of 0.9% sodium chloride solution intravenously and in the absence of any substantial salt losses, is not clear. However, it is possible the "fall" in serum Na from 112 to 98 mEq/L was not real but due to the lipidemia. This would be consistent with the serum osmolality (241 mOsm/L), which was higher than the Na (98 mEq/L) and BUN (39 mg/dL) values would suggest. The initial elevated BUN and hemoglobin values are consistent with intravascular contraction, but there never were any other signs of hypovolemia to suggest this played a role in his disorientation.

Since minimal-change nephrotic syndrome is often a prolonged and frequently relapsing condition and since many families will embrace a "salt-free" diet as easier to follow routinely rather than only during periods of edema, it is important to emphasize the danger of too severe salt restriction. Salt restriction is not indicated during periods of clinical remission and should not be encour-

Autoimmune Thyroiditis With Thyrotoxicosis Eventuating in Hypothyroidism in a Short Interval

Autoimmune thyroiditis may appear as thyrotoxicosis,[1,2] but it usually leads to hypothyroidism, although that evolution may take years.[3-6] We describe a 14½-year-old girl whose condition was in the thyrotoxic phase, who required antithyroid drugs, and who became hypothyroid in three months. The shortest interval previously described was six months.[5]

Report of a Case.— This 14½-year-old girl was admitted to the hospital with complaints of malaise, weight loss, sore neck, and mild fever of one week's duration, preceded by cough and rhinitis. Three days prior to admission, tender swelling was noted in the anterior side of the neck. On admission, she had a temperature of 38.9 °C, a pulse rate of 120 beats per minute and a blood pressure of 120/80 mm Hg. Her skin was warm and moist. The thyroid gland was threefold enlarged, soft and rubbery in consistency, and nontender, without local inflammatory signs. No thyroid nodules or regional nodes were noted. A bruit was present over both lobes of the thyroid gland. She was complaining of pain in the anterior side of the neck, radiating to the right ear. No eye abnormalities or tremor were seen, and deep tendon reflexes were normal. Family history showed no thyroid disease or autoimmune diseases.

White blood cell count was 7,000/cu mm. The ESR was 15 mm/hr; serum T_3 uptake was 47.3% (normal, 25% to 35%); T_4 value was 15.3 μg/dL (normal, 5 to 13.7); free T_4 index was 23.4% (normal, 4.4 to 15.7%); radioactive iodine uptake was 20% at 4.5 hours and 27% at 24 hours, without discharge by $KClO_4$, which was given at 4.5 hours. Antithyroglobulin antibody titer was 1:10 (normal, < 1:20). Antimicrosomal antibody titer was 1:25,600 (normal, < 1:100).

She was given aspirin (acetylsalicylic acid) at 60 mg/kg/day for 3.5 weeks. Propranolol hydrochloride, 160 mg daily, divided in four doses, was started on the second hospital day when she had increasing enlargement of the thyroid gland, bounding pulse, an aortic insufficiency murmur, and blood pressure of 140/50/0 mm Hg. Because of development of an allergic rash, propranolol therapy was discontinued three weeks later, and she was given propylthiouracil, 150 mg every eight hours. Five weeks later, she was clinically euthyroid. Propylthiouracil therapy was discontinued at three months of treatment because of suspicion of hypothyroidism. The thyroid gland was still twofold enlarged.

Two months later (six months after onset of disease), she returned complaining of tiredness, poor appetite, and generalized puffiness of one week's duration. She had cool, dry skin, a puffy face, and increased supraclavicular fat pads. The thyroid gland was not enlarged. Laboratory findings were as follows: serum T_3 uptake, 23.9%; T_4, less than 2.0 μg/dL; free T_4 index, less than 2.0%; TSH, 50.7 IμU/mL. She was given levothyroxine sodium (L-thyroxine), 0.25 mg daily.

After 15 months of treatment, levothyroxine was discontinued to assess her thyroid status. Thyroid tests were repeated six weeks after treatment was discontinued with the following results: serum T_3 uptake, 27.7%; T_4, 10.0 μg/dL; free T_4 index, 11.4%; TSH, 3.7 IμU/mL; antithyroglobulin antibody titer, 1:640; antimicrosomal antibody titer, 1:6,400. Her thyroid gland was of normal size and soft in consistency when we saw her again three months after treatment was discontinued. She remained clinically euthyroid.

Comment.—The diagnosis of autoimmune thyroiditis was made on the basis of an elevated antibody titer.[7] Such high antibody titers would be unexpected in classical Graves' disease, but they are associated with lymphocytic infiltration of the thyroid gland.[8]

The tests that should differentiate subacute from chronic lymphocytic thyroiditis gave conflicting information. The radioactive iodine uptake was greater than would be expected for subacute thyroiditis[1] although the tender gland and pain referred to the ear suggested that condition. However, radioactive iodine was not discharged from the gland when potassium perchlorate was given, as would be expected in autoimmune thyroid disease.[7] In the absence of histological confirmation, the diagnosis of Hashimoto's thyroiditis in this patient cannot be considered established. However, the clinical course, although accelerated, is in keeping with lymphocytic thyroiditis.

When subclinical hypothyroidism was suspected after three months of propylthiouracil treatment, we had to differentiate propylthiouracil toxicity from spontaneous development of hypothyroidism. Hypothyroidism secondary to propylthiouracil usually lasts only for a few weeks and is accompanied by an enlarging thyroid gland. But two months later, the previously enlarged thyroid gland was barely palpable, suggesting spontaneous development of hypothyroidism.

The course in this patient is unusual in that transient hypothyroidism followed thyrotoxicosis in so short a period of time. This sequence of events calls attention to the necessity of maintaining close contact with patients who have thyroiditis.

Necrotizing Enterocolitis

Sir.—I read with interest the article "Epidemic Occurrence of Neonatal Necrotizing Enterocolitis," by Guinan et al (JOURNAL 133:594-597, 1979). The observation that almost all infants (38 of 39) were fed prior to the onset of necrotizing enterocolitis (NEC) is in agreement with other studies.[1-5] In one retrospective, case-control study similar in design to that of Guinan et al, 54 of 54 infants were fed prior to NEC onset, whereas only 63% of 98 matched controls ($P < .001$) were fed at a comparable time.[2] These findings strongly suggest an etiologic relationship between feeding and NEC. Guinan et al do not tell us how many of their controls were fed, and this would be a statistic of some interest.

In an unpublished survey carried out in the early 1960s of feeding practices in six premature nurseries in the metropolitan New York City area, I found that slow, gradual feeding increments were the rule; also, that the feeding of premature babies was generally regarded as an important and difficult task that required considerable knowledge and experience. A senior nurse with a special interest in feeding often had the responsibility for ordering feeding volumes. The infant's size, age, clinical status, and especially his tolerance to feedings all entered into the feeding equation. Now, in our modern, very complex neonatal units, there has been, I fear, a downgrading of the importance of feeding and, at times, assignment of this responsibility to inexperienced personnel. In addition, concern with regard to possible (but unproved) effects of undernutrition on the developing brain has created an urgency to increase caloric intake. In this climate, it should not be surprising that epidemics of NEC may occur. Indeed, it may very well be that the outbreak of NEC in the United States since the mid-1960s is itself an epidemic that has resulted largely from a radical change in the manner in which we feed our premature infants. The current situation is reminiscent of that with pellagra in the early part of this century. Pellagra, like NEC, occurred in institutional epidemics and there were many who believed the disease to be infectious.[6]

6. Terris M: *Goldberger on Pellagra.* Baton Rouge, La, Louisiana State University Press, 1964, pp 10-11.

In Reply.—I agree with Dr Goldman that the relationship between changed feeding patterns for premature infants and the increased incidence of neonatal NEC is striking. Unfortunately, we were unable to study feeding patterns within each hospital before and during the epidemics for evidence of significant change. In our studies, only two of the 53 control infants were not fed within a time period comparable to that of case infants. The number of infants fed within 24, 48, or 72 hours of birth did not differ between the two groups, nor did the number of infants who received their first oral feeding after the fifth day of life. We were able to compare the average daily mean volume of formula received by case and control infants during the first five days of life only in hospital C, and found no significant difference between the two groups.

Book et al[1] showed that carbohydrate malabsorption preceded the development of NEC in affected infants, and that control infants had significantly less evidence of a carbohydrate malabsorption. Carbohydrate overloading of the absorptive capacity of the newborn intestinal tract and consequent passage of the carbohydrate to the lower intestinal tract could provide gas-forming bacteria with increased substrate for gas production. If infants are unable to absorb or expel the gas, the buildup of gas pressure may be sufficient to cause pockets of intestinal necrosis. Thus, at least three conditions would be hypothetically necessary for development of disease: (1) carbohydrate in the colon, ileum, or jejunum; (2) colonization of these areas with gas-forming bacteria; and (3) either impairment of intestinal motility that prevents expelling the gas or inability of the intestine to absorb the particular gases formed.

The histopathology of NEC, with notable lack of polymorphonuclear leukocytes, is not consistent with a colitis, but with a pressure necrosis.[2] Areas of necrosis do not follow a vascular pattern and are often bound by areas of apparently normal intestinal tissue. Perhaps the disease would be more appropriately named "necrotic gut syndrome of the newborn," and this change in concept might alert investigators to search for causes other than causes of colitis in this syndrome. Dr Goldman's suggestions are timely and provocative, and are greatly appreciated.

CORTISPORIN® OTIC SUSPENSION Sterile (Polymyxin B-Neomycin-Hydrocortisone)
DESCRIPTION: Each cc contains:
Aerosporin®
(Polymyxin B Sulfate) ..... 10,000 units
Neomycin sulfate ..... 5 mg
(equivalent to 3.5 mg neomycin base)
Hydrocortisone ..... 10 mg (1%)
The vehicle contains the inactive ingredients cetyl alcohol, propylene glycol, polysorbate 80, water for injection and thimerosal (preservative) 0.01%.
INDICATIONS: For the treatment of superficial bacterial infections of the external auditory canal caused by organisms susceptible to the action of the antibiotics, and for the treatment of infections of mastoidectomy and fenestration cavities caused by organisms susceptible to the antibiotics.
PRECAUTIONS: This drug should be used with care in cases of perforated eardrum and in long-standing cases of chronic otitis media because of the possibility of ototoxicity caused by neomycin.

CORTISPORIN® OTIC SOLUTION Sterile (Polymyxin B-Neomycin-Hydrocortisone)
DESCRIPTION: Each cc contains:
Aerosporin®
(Polymyxin B Sulfate) ..... 10,000 units
Neomycin sulfate ..... 5 mg
(equivalent to 3.5 mg neomycin base)
Hydrocortisone ..... 10 mg (1%)
The vehicle contains the inactive ingredients cupric sulfate, glycerin, hydrochloric acid, propylene glycol, water for injection and potassium metabisulfite (preservative) 0.1%.
INDICATIONS: For the treatment of superficial bacterial infections of the external auditory canal caused by organisms susceptible to the action of the antibiotics.
PRECAUTIONS: This drug should be used with care when the integrity of the tympanic membrane is in question because of the possibility of ototoxicity caused by neomycin.
ADVERSE REACTIONS: Stinging and burning have been reported when this drug has gained access to the middle ear.
CONTRAINDICATIONS, WARNINGS, PRECAUTIONS AND ADVERSE REACTIONS COMMON TO BOTH PRODUCTS
CONTRAINDICATIONS: These products are contraindicated in those individuals who have shown hypersensitivity to any of the components, and in herpes simplex, vaccinia and varicella.
WARNINGS: As with other antibiotic preparations, prolonged treatment may result in overgrowth of nonsusceptible organisms and fungi. If the infection is not improved after one week, cultures and susceptibility tests should be repeated to verify the identity of the organism and to determine whether therapy should be changed.
When using neomycin-containing products to control secondary infection in the chronic dermatoses, such as chronic otitis externa, it should be borne in mind that the skin in these conditions is more liable than is normal skin to become sensitized to many substances, including neomycin. The manifestation of sensitization to neomycin is usually a low grade reddening with swelling, dry scaling and itching; it may be manifest simply as a failure to heal. During long-term use of neomycin-containing products, periodic examination for such signs is advisable and the patient should be told to discontinue the product if they are observed. These symptoms regress quickly on withdrawing the medication. Neomycin-containing applications should be avoided for that patient thereafter.
PRECAUTIONS: If sensitization or irritation occurs, medication should be discontinued promptly. Patients who prefer to warm the medication before using should be cautioned against heating the solution above body temperature, in order to avoid loss of potency.
Treatment should not be continued for longer than ten days. Allergic cross-reactions may occur which could prevent the use of any or all of the following antibiotics for the treatment of future infections: kanamycin, paromomycin, streptomycin, and possibly gentamicin.
ADVERSE REACTIONS: Neomycin is a not uncommon cutaneous sensitizer. There are articles in the current literature that indicate an increase in the prevalence of persons sensitive to neomycin.

"...safe and effective, both bacteriologically

Just specify... depending on the condition:

CORTISPORIN®
Otic Solution Sterile (polymyxin B-neomycin-hydrocortisone)

A clear solution (does not have to be shaken) providing clear visualization of field—indicated *only* for infections of the external ear canal due to susceptible organisms; stinging and burning have been reported when the drug has gained access to the middle ear

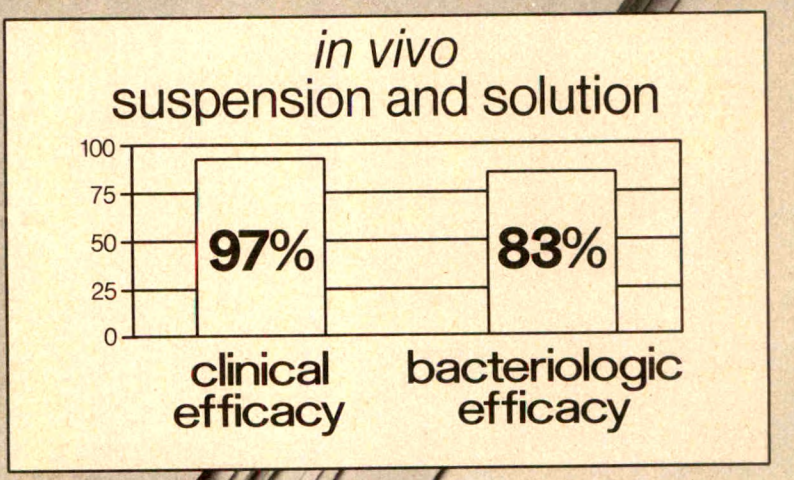
CORTISPORIN®
Otic Suspension Sterile (polymyxin B-neomycin-hydrocortisone)

A white suspension—indicated *both* for infections of the external ear canal as well as infections of mastoidectomy and fenestration cavities caused by susceptible organisms

and clinically in the treatment of diffuse external otitis."*

outstanding clinical results

In a recent study of 239 patients (283 ears), Cortisporin® Otic Solution Sterile and Suspension Sterile both achieved a clinical efficacy rate of 97% and a bacteriologic efficacy rate of 83%.



Two otic products—Solution and Suspension... give you the assurance of:

- therapeutic success, clinical acceptance
- wide range of antibacterial activity, including many strains of *Pseudomonas aeruginosa,* the most common otic pathogen, as well as *Proteus* and staph
- direct anti-inflammatory action, relieving associated itching, swelling, and pain
- acid pH to help restore normal acidity of the ear canal
- economy for your patients—usually less cost than with other comparable otics

CORTISPORIN® Otic Solution/Suspension
(polymyxin B-neomycin-hydrocortisone)

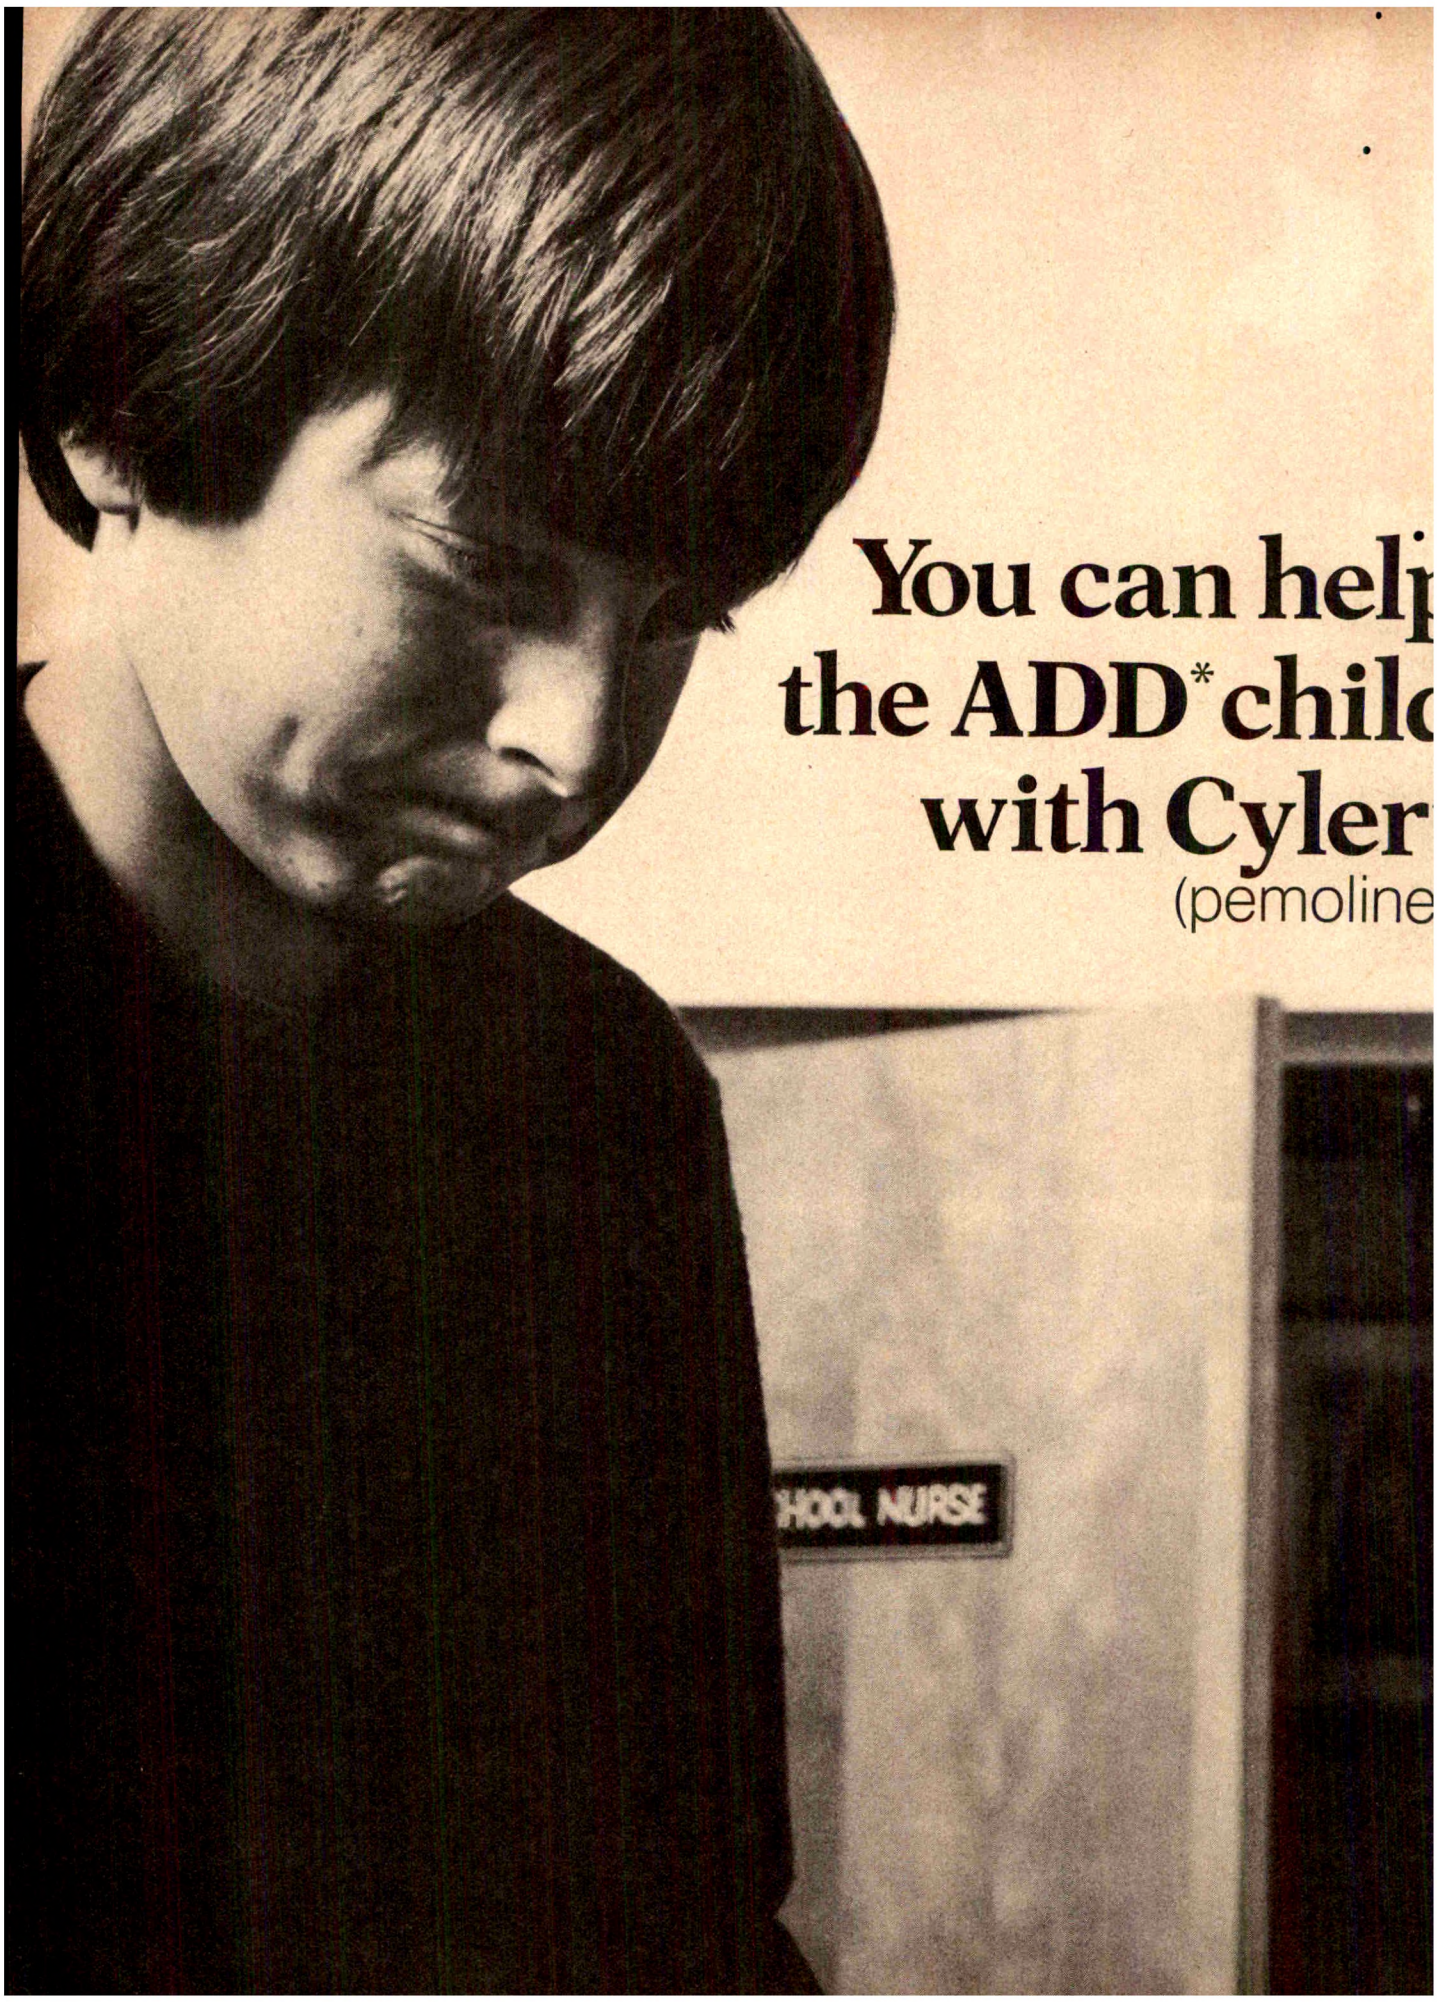
ONE HUNDRED YEARS WELLCOME

Burroughs Wellcome Co.
Research Triangle Park
North Carolina 27709



You can help
the ADD* child
with Cylert
(pemoline
HOOL NURSE

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® (pemoline) C IV

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

ABBOTT

9083319

Cylert® (pemoline)

DESCRIPTION: CYLERT (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

CYLERT (pemoline) is supplied as tablets for oral administration.

CLINICAL PHARMACOLOGY: CYLERT (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

There is neither specific evidence which clearly establishes the mechanism whereby CYLERT produces its mental and behavioral effects in children, nor conclusive evidence regarding how these effects relate to the condition of the central nervous system.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. CYLERT is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

CYLERT (pemoline) has a gradual onset of action. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

INDICATIONS: CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS: CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS: CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS: Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS: Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT; a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities, nystagmus and nystagmoid eye movements, and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE: Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION: CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

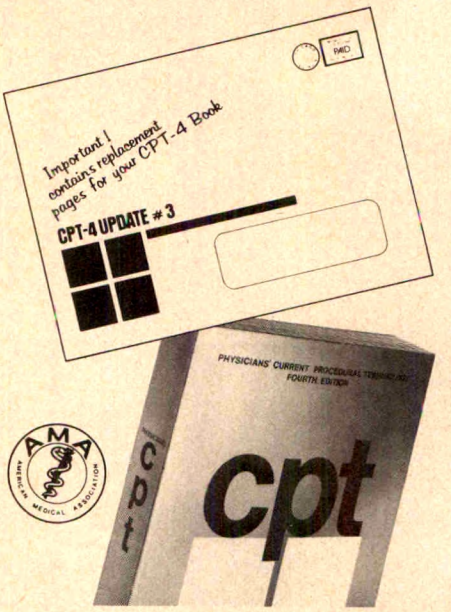
Announcing... UPDATE No.3 for CPT-4!



That's what keeps CPT-4 the most current medical reporting system you can use!

The 4th Edition of *Physicians'* CURRENT PROCEDURAL TERMINOLOGY is the only coding system that provides new and revised terminology on a regular, automatic basis. This latest update, Summer 1979, marks the third update since CPT-4 was published in 1977.

The updates are on self-adhering pages that are affixed to the pages they replace in CPT-4. To activate the automatic update mechanism, you simply return the postage-free card in the book.

CPT-4 is a uniform coding system to accurately designate medical, diagnostic, and surgical services in terms of a uniform language among physicians, patients, and third parties.

Shouldn't you be using the most current coding system available?

Order two—one for yourself, one for your medical records clerk.

Order Dept., OP-41
American Medical Association
P.O. Box 821
Monroe, Wisconsin 53566

Please send me _____ copy(ies) of *Physicians CURRENT PROCEDURAL TERMINOLOGY*, 4th Edition, OP-41. Price: $12 per copy. Enclosed is my check (payable to AMA) for $_____. Allow 4-5 weeks for delivery.

Books

Fetal Growth in Humans, by Herbert C. Miller and Allen Merritt, 180 pp, Chicago, Year Book Medical Publishers Inc, 1979.

This book reports the findings of an exhaustive five-year study made personally by the authors. The main objectives of the study were as follows: (1) to construct standards for presumably normal fetal growth from anthropometric data of newborn infants who were "free from all known growth retarding influences in utero"; (2) to expand the number of atypical fetal growth patterns presently being recognized and to compare infants with these atypical patterns against the normal standards; and (3) to describe the causes and consequences of atypical fetal growth.

The authors thus set themselves a formidable task, and it would have been impossible to satisfy all their potential critics. Most clinicians and research workers in this field would agree that the criterion of slow fetal growth in terms of weight for gestational age at birth is not entirely satisfactory. But it has, at least, the advantages of general acceptance and simplicity. This allows for comparisons between studies made in different populations and under varying conditions. It is also still possible, within groups of small-for-date (or large-for-date) babies ascertained by a weight criterion, to subcategorize them according to their length and/or head circumference measures and thus to take account of their heterogeneity. Statistical validation is important if different patterns of atypical fetal growth are categorized ab initio by indices comprising two interdependent variables.

The control group on which the anthropometric data on normal infants were obtained was a highly selected sample since two of every three full-term infants and about 85% of all premature infants were excluded because of "some fetal or maternal growth-retarding factor." Among the latter, particular emphasis was paid to a group of maternal "behavioural conditions" that the authors consider modifiable and largely a matter of maternal choice. As well as smoking, drug addiction, and excessive alcohol consumption during pregnancy, factors such as delivery before the 17th or after the 35th birthday, lack of antenatal care, low weight gain during pregnancy, and low prepregnancy weight for height were also included in this "behavioural" group. However, short stature and very low prepregnancy weight, alone, were not considered growth-retarding factors at all. The only growth-accelerating factors that prompted exclusion from the control group were gestational diabetes and diabetes mellitus, and no account was taken of the large biological variations in size at birth. The arbitrary nature in which some factors were included or excluded does not lend credibility to the findings based on comparisons within and between the groups.

Despite the aforementioned reservations, this book is packed with a large amount of useful and interesting information, and it gives a refreshing new look at a subject that has been the basis of intense investigation during the last ten to 15 years. There is an interesting chapter on twin pregnancy; and the observation that, among control infants, the incidence of small head circumference was 0.8% for obese mothers, compared with 9.7% for slender mothers and 8.7% for underweight mothers has important implications for sonographers who judge fetal size and maturity by BPD techniques.

Clinicians and research workers interested in somatic growth will all find something new, or provocative, in this book. However, I doubt whether many will actually want to own it.

MARGARET OUNSTED, DM
John Radcliffe Hospital
Oxford, England

Abnormal Fetal Growth: Biological Bases and Consequences, edited by Frederick Naftolin, 289 pp, $11.95, Berlin, Dahlem Konferenzen, 1978.

The provenance of this book was a Dahlem workshop held in West Berlin in February 1978. Unlike most symposia, no lectures were given. Selected participants were asked to write background articles providing a review of their own particular aspect of the subject. These were intended to be provocative as well as informative. They were circulated to the other participants and questions formulated before the meeting so that detailed discussions could begin, forthwith.

It is clear that the participants were carefully chosen and that each was of high repute in his own discipline. They ranged from cell biologists, embryologists, experimental physiologists, and agriculturalists to research workers and clinicians working mainly in obstetrics and pediatrics.

The structure of the workshop was such that after the opening plenary sessions, four separate groups were formed to discuss different aspects of the subject. Each group presented a report at the end of the meeting. The structure of the book follows this patten and reflects the intensive thought and intellectual activity generated.

The 11 background articles in this book are all of a high standard. Long lists of references are not given. Instead, care has been taken to quote the most relevant and pertinent. Apart from a few classics such as Walton and Hammonds' well-known crossbreeding experiments, they report work mainly done in the present decade.

The first section is the "Definition, Epidemiology and Identification of Abnormal Fetal Growth." The background works on concepts and criteria and on present methods of intrauterine diagnosis are concerned primarily with human beings, and the essential points that emerged in discussion are outlined in the group report. (D. Hull, rapporteur). A brief resume of pathological factors is given, but emphasis was mainly directed to biological phenomena. Among maternal factors, the concept of maternal constraint is discussed, and it is explained that, in this context, it is used to mean that characteristic transmitted by the mother to her daughters that influences the fetal growth of all her young of both sexes and that is transmitted through the female line. The concept of "brain sparing" was considered and the group concluded that if the expression were not so firmly entrenched, they would have recommended that it be dropped. "As it is, it must be more realistically described in order to avoid any of the optimism it often engenders." This group pointed out that the most important consequence of abnormal fetal growth is its long-term, even postnatal effects; and they suggested that perhaps this should be the yardstick by which we judge the influences that produce abnormalities in fetal growth, or the interventions that are aimed at preventing them.

However, postnatal consequences were not within the remit of this workshop. It is hoped that a subsequent one will be convened to consider them.

The second section is concerned with early development, and includes works on experimentally induced chromosome aberrations, mechanisms of embryonic organ formation, and the importance of growth factors. The group report (P. W. Nathanielsz, rapporteur) analyzes the various basic mechanisms as an ordered sequence: prezygotic, peri-implantation, organogenesis, and maturation. It seems that synchronization between embryo and maternal organism may be the primary focus of action for many of the genetic and environmental factors that were discussed; and the group concluded that a better understanding of the basic mechanisms is an essential prerequisite to control and possible therapy in prenatal and postnatal life.

The last two sections of the book are concerned with fetoplacental growth, and they describe wide-ranging studies on other mammals (rats, rabbits, guinea pigs, sheep, rhesus monkeys, and chickens, etc). The background articles explore the factors regulating the growth of the placenta, deviations in organ growth and maturation, substrate availability, enzymes, and the regulation of placental blood flow and oxygen transfer in relation to fetal growth. There is also a salutary chapter by K. Benirshke on the relevance of comparative studies in animals. The third group report (J. R. G. Challis, rapporteur) gives a summary of our present knowledge about the main influences, interactions, and mediating factors affecting placental and fetal growth. The final report (F. D. Frigoletto, rapporteur) considers in depth the many areas of ignorance that still exist, including cautionary tales, the problems of "animal models," the fetoplacental unit as a two-way process, and the question of therapy for the growth-retarded fetus. Some worthwhile research directions are outlined.

In recent years, there have been a number of publications reporting the proceedings of symposia on the subject of fetal growth. This is the best yet. It reflects five days of intensive discussion and integration by a multidisciplinary international group of experts. This is condensed into one volume. The contents would be of interest to all practising obstetricians and pediatricians. The large number of research workers in this field will find it compelling reading, and they are well advised to have a copy of their own.

Atlas of the Newborn, by Neil O'Doherty, 412 pp, 530 illus, $29, Philadelphia, Harper & Row Publishers Inc, 1979.

The old chestnut that a picture is worth 1,000 words would surely justify the publication of a color atlas of the newborn. The explosion of knowledge on the care of the neonate has reached the encyclopedic state, with each new volume exceeding the previous one in a mass of verbal detail. Thus, a text that depicts visually the essentials of neonatology would be most welcome. To that end, Neil O'Doherty of the University College of Dublin has assembled more than 500 color photographs and has authored a succinct accompanying text. The result is an atlas of the newborn that emphasizes the physical characteristics of the newborn, both normal and abnormal.

The *Atlas* is organized into six separate and roughly equal sections, entitled: "The Normal Infant and His Trivial Complaints," "Low Birth Weight Babies," "Trauma," "Infection," "Congenital Abnormality," and "Skin Defects." The great majority of the photographs are of physical signs, and only a rare roentgenogram or a surgical or pathological specimen is presented.

From a technical point of view, by and large the *Atlas* succeeds. The quality of the color photography exceeds that found in most textbooks, both in clarity and in color reproduction. This is especially true in the chapter on skin defects. As to content, however, serious deficiencies exist. This is most glaring in the section on infection and congenital anomalies. Diseases with classic external physical characteristics, such as syphillis and herpes, are not pictured at all, whereas others are given short shrift. Similarly, whereas trisomy 21 is pictured with all its characteristic features, most other chromosomal entities either are not pictured at all or are incompletely presented. Thus, as a guide for the clinical evaluation of congenital abnormalities, this section pales in comparison to Smith's classic text *Recognizable Patterns of Human Malformation,* or even the short *Atlas of Mental Retardation Syndromes* of Gellis and Feingold.

The strongest chapters are those that picture the newborn infant with all his normal and minor variations. As a guide to the inexperienced student or physician learning physical diagnosis, this section is unrivaled. Surprising, however, is the unsystematic approach to the presentation of the low birth weight infant. Conspicuous by its absence is a pictorial representation of the features of Dubowitz's examination. In contrast, whereas the section on birth trauma is quite vivid and emphasizes the variety of iatrogenic insults that are inflicted on the newborn, one must wonder why there was need to present 14 different pictures of cephalohematoma. This disproportion between the number of pictures and the incidence or seriousness of the physical defect is quite common. Even less successful, in general, is the accompanying text. It is all too often too detailed for a commentary on the pictures and inadequate as a textbook of neonatology.

The general spottiness of the material presented suggests that the contents of the *Atlas* were determined by the available illustrations, rather than the converse method of choosing the subject matter and then seeking the appropriate photographs. As a result, the *Atlas,* while offering a series of superb photographs at a very reasonable price, cannot be recommended as a critical part of the pediatrician's library.

Adolescence, by Doris Odlum, 162 pp, $10.50, Westport, Conn, Technomic Publications Inc, 1979.

Adolescence is the critical period of human development that encompasses the physical and psychological changes transforming the child into the adult. Though the preface indicates that this book is written for anyone, it seems to be an overview of this process of adolescence for parents of teenagers. It was first published more than 20 years ago under the title *Journey Through Adolescence,* and indeed it watchfully takes

the reader through the Alice-in-Wonderland evolution of the child into the adult. It was written by a psychiatrist, who uses principles of adolescence along with brief personal cases and literary quotations to clarify her discussions. Theories of adolescence are translated into practical explanations of why a teenager does specific, seemingly bizarre actions, so that parents can try to understand their own or other teenagers. Dr Odlum mixes in a delightful personal seasoning, based on much experience with, and obvious enjoyment of this age group.

The book is divided into 15 sections that cover many aspects of youth, including health, home, school, employment, friendships, cognitive thinking, and moral values. Concepts of adolescent sexuality are covered throughout the book, but there are specific sections on "adolescent pleasures," masturbation, sex, "love," and homosexuality.

There are many comments that parents will find valuable and even reassuring in this book. Parents will especially note Dr Odlum's emphasis on a stable home with a good parental marriage, and her view that despite the complex turmoil of adolescence most emerge intact from their teenager years. Also covered are the concepts of teenage ambivalence, magical thinking of teens with regard to their own sexuality, the differences in male and female sexual responses, and the need of youth for some limits.

There are good discussions of the need to treat each teenager individually, the oft-noted parental concern with their teenager's friends ("good vs bad"), the problem of sibling rivalry, the normal guilt feelings of parents who have a handicapped child, and even the difficulty of dealing with education and employment in an increasingly specialized environment. Parents will also read with great interest the explanations given for the loud teenage music, their hysterical reaction to rock stars, and even the "mod" teen dress phenomenon. The section on masturbation is interesting, as parents are told it may play a useful role in teenagers lives by the reduction of sexual tension.

However, the question remains whether or not this book is useful for the pediatrician seeking careful documentation of the process called adolescence. I think not. The medical advice tends to be spotty, occasionally inaccurate and often not tightly described. Girls are advised not to go swimming while menstruating, and acne is related to overactive sebaceous glands with dust settling in enlarged pores. It is stated that there are almost no physical illness teenagers are prone to develop. Constipation and foot disorders are singled out for discussion in this light. Parents are advised to be concerned about their teenager's bowel habits. There is no mention of Tanner staging, physiologic leukorrhea, and many other important medical concepts.

A discussion of menstruation does not mention that many girls view menarche as a venereal disease or as evidence of injury. Fathers are told that they are shy about telling their teenage daughters sexual information, but not of the normal Oedipal distancing that occurs between them. Theories of adolescence are not presented in enough detail and not identified as to their origins. Established theory and opinion become merged. Many of the comments apply to middle-class teenagers in England and are not always transferable to other groups.

Finally, I do not mean to be overly critical. This book presents a colorful and worthwhile overview of adolescence for parents, and for pediatricians who are parents of teenagers and who wish to enjoy a book from that perspective. If the physician wishes to have information about the sphere of adolescent medicine that will provide critical information that has been peer-reviewed and will aid in a professional evaluation and treatment of teenaged patients, there are other references to use. Adolescent medical literature is growing, and *carefully* detailed works are needed.

DONALD E. GREYDANUS, MD
Division of Adolescent Medicine
Department of Pediatrics
University of Rochester Medical Center
Rochester, NY 14642

Atlas of Clinical Conditions in Pedodontics, by R. Rapp and G. B. Winter, 142 pp, 478 illus, Chicago, Year Book Medical Publishers Inc, 1979.

This atlas is a collection of clinical photographs and roentgenographic illustrations of pathologic conditions that involve the oral cavity, face, and cranium. Covered are hereditary disorders, developmental problems, infectious diseases, trauma, neoplasms, and the volume includes a variety of pictures that demonstrate the limits of normality. The authors are well-known, highly respected pedodontists. Although this book might be of greater interest to dentists, it could be of value to the pediatrician confronted with a pathologic oral condition.

The 478 illustrations are nicely reproduced, with reasonably accurate color rendition of the tissues involved. The roentgenograms have been duplicated clearly and should be readily understood even by those not familiar with intraoral roentgenograms. The authors have chosen to depict most of the commonly occurring conditions seen by the clinician. They have also included several rarer conditions, such as trisomy 13-15 syndrome and oculoauriculovertebral dysplasia. In most cases, the illustrations depict a representative example of the disease as it is usually seen. In a few instances, a severe or unusual manifestation is illustrated.

The book is divided into sections that deal with the cranium and face, the teeth, gingiva, oral mucosa, palate, tongue, jaws, and limbs. This last section depicts conditions related to oral pathology or referred to in the earlier sections (thrombocytopenia, syndactyly, osteogenesis imperfecta, etc). The nomenclature used is familiar, and the British spellings are only a mild distraction.

The *Atlas* is not intended for use as a textbook. Written descriptions are concise and limited to a brief history or explanation of the condition. No attempt is made to explain treatment options or prognosis. The organization of the book into "anatomic" sections makes it easier to use as a reference to help establish a diagnosis. This atlas compares favorably to others that deal with oral pathology and pedodontics, and will be of special interest to those devoted to the health care of children.

Perinatal Coagulation, by William E. Hathaway and John Bonnar, 235 pp, $17.50, New York, Grune & Stratton Inc, 1978.

The specialty of perinatology has blossomed and burgeoned during the past few years and has brought together a health team of obstetri-

cians, neonatologists-perinatologists (nepediatricians), clinical nursing specialists, and technicians whose primary concern is the pregnant mother and her newly born infant. This symbiotic unit has special medical problems, and a firm understanding of the physiology and pathophysiology of interacting systems has obvious merit for those charged with its care. Thus, it is appropriate that two authorities in the field, Dr William Hathaway, a pediatric hematologist whose major contributions have been in the field of neonatal coagulation, and Dr John Bonnar, an obstetrician-gynecologist with a particular interest in hemostasis during pregnancy, have collaborated in preparing this interesting monograph. A common problem in any perinatal center today is the 1,100 g premature infant with respiratory distress syndrome and ecchymoses, oozing from puncture sites, thrombocytopenia, prolonged prothrombin time (PT) and partial thromboplastin time (PTT), decreased fibrinogen level, raised levels of fibrin split products, and decreased activities of factors II, VII, IX, X, and XII. Similarly, obstetrical patients with life-threatening massive hemorrhage and deep-vein thrombosis, and pulmonary embolism will tax the clinical skills of most physicians.

The problem with perinatal medicine is partly political and partly intellectual. As an independent administrative unit, divisions of perinatology have become liberated from their parent department of pediatrics. In some units, less rather than more interaction with pediatric subspecialists (eg, hematologists, cardiologists) has evolved with the self-recognition of the perinatologist-neonatologist as the "compleat pediatrician." Drs Hathaway and Bonnar state in the preface that the purpose of their new textbook is to synthesize the state of the art of perinatal coagulation for the "clinicians responsible for the care of the mother and her infant." Although it is unlikely that the same clinician treating deep-vein thrombosis and pulmonary emboli in a 32-year-old primigravida would write orders for the 1,100 g infant with disseminated intravascular coagulation (DIC) described earlier, the aim of this textbook is to unite the study of coagulation, normal and abnormal, occurring in the perinatal period. In providing an overview of the normal physiology of coagulation and the associated clinical disorders, the authors perform a creditable service. The hematologist, who should be consulted about major bleeding problems, will find that other available textbooks cover the physiology of coagulation in much greater detail and provide the required information to diagnose and manage these problems.

If the purpose of the book is to educate the obstetrician and the neonatologist, it will do an admirable job. The most fascinating reading concerns those states of intravascular coagulation in the mother or in the fetus that can cause similar changes in the other, eg, retained dead fetus or placental abruption. Similarly, the relationship between anticoagulation therapy in the mother and the fetus are well covered (eg, heparin does not cross the placenta, but orally administered anticoagulants depress levels of factors II, VII, IX, and X in the fetus). It is unclear whether mothers suffering from thromboembolic complications and taking warfarin should breast-feed their infants. The authors say no, but the only study cited showed that breast milk of such mothers had undetectable levels of anticoagulant. The discussion of possible mechanisms of intraventricular hemorrhage in the neonate is complete, but recommendations for therapy could be more detailed.

A relatively common clinical problem is neonatal isoimmune thrombocytopenia (ITP). In the "neonatal" chapter, cesarian section is recommended for subsequent pregnancies, whereas a more conservative approach is advocated in the "pregnancy" chapter. The reader could benefit from specific advice: How long should the neonate be treated with corticosteroids? Should the mother be given corticosteroids prior to delivery of her second baby if the first had neonatal ITP? What happens if transfused maternal platelets have a short time of survival? The possibility of subclinical maternal ITP must be suspected in this situation. Only the barest details of inherited hemorrhagic disorders are provided. The major screening tests are covered superficially, and references for some (eg, thromboelastogram, recalcification time, thrombotest, thrombin time, reptilase time, and clot stability test) are not provided. The uninitiated would have little appreciation for the strengths and weaknesses of each of the suggested laboratory tests. More tables and figures would add to the clarity of presentation, and some could be improved by dealing only with perinatal disorders rather than with abnormalities affecting older children.

A major problem facing neonatologists is the laboratory characterization and definition of DIC in the premature infant. In the authors' laboratory, the diagnosis of DIC is based on platelet count, PT, PTT, fibrogen degradation products, fibrinogen, and blood smear tests. If all are normal, DIC is not present. The problem arises when the results of some but not all of these studies are abnormal. A more detailed definition of DIC is needed and, again, data based on the authors' own experience would be extremely helpful. More details regarding the duration of therapy with heparin in DIC, and the best method for monitoring heparin effects are needed as well. The measurement of whole-blood clotting time in the neonate is fraught with technical problems and error, particularly if left in the hands of fatigued house officers at 3 AM.

The last chapter, on coagulation changes in preclampsia, eclampsia, and fetal growth retardation, provides some of the most interesting material in this book. Fibrin deposition and intimal lipid in uteroplacental arteries occur in preclampsia and are similar to findings in atheroma, atherosclerosis, and rejected renal transplants, suggesting a similar mechanism of pathogenesis. The results of a controlled study using low dosage heparin and a platelet antiaggregating agent (dipyridamole) in women at high risk for eclampsia and fetal growth retardation will be eagerly awaited. Such studies reflect the real objectives of collaborative clinical and laboratory investigation in perinatal centers. On that note, this new text should be useful to nurses, medical students, residents, and attending physicians working in university-affiliated perinatal units, and to generalists (obstetricians and pediatricians) in community hospitals who wish to brush up their knowledge of perinatal coagulation.

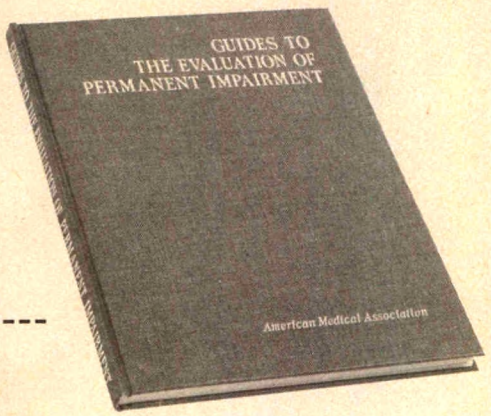
Do you have GUIDES TO THE EVALUATION OF PERMANENT IMPAIRMENT on your reference shelf?

If not, now is the time to fill the void!

Guides to the Evaluation of Permanent Impairment contains a series of practical guides for the rating of physical and mental impairment of all systems of the body. Published by the American Medical Association, this important volume will assist you in discharging your responsibility to patients who are seeking benefits from the various agencies and programs serving the disabled.

Each guide provides recommended percentage values related to the criteria given. Numerical values offer a practical means of expressing and calculating the extent of permanent impairment and encourage accurate, equitable, and uniform evaluation. Methods of impairment calculation are uniform, are explained in detail with examples, and need a minimum of computation. A Combined Values Chart is provided for easily assessing any combination of impairments.



A partial table of contents includes:

- The Central Nervous System
- The Peripheral Spinal Nerves
- The Endocrine System
- The Digestive System
- The Extremities and Back
- Mental Illness
- The Visual System
- The Cardiovascular System

NOW PETER

Attention Deficit Disorders* under control...
His natural abilities are coming through

Now Peter's enjoying more things at play as well as in school. He works better with his teacher and classmates... likes doing things with his dad... gets more natural pleasure out of family and friends.

Now that his concentration is improved, his natural abilities are coming through. He's functioning better. Under a well-integrated program of treatment for Attention Deficit Disorders (ADD), hyperactivity and impulsiveness are markedly reduced.

Ritalin (methylphenidate) can be a vital part of his regimen. With adjunctive use of Ritalin, many ADD children are better able to control hyperkinetic behavior —act in a more natural and appropriate manner.

A 20-year record of proven efficacy

Over the years, Ritalin has become an established choice for pharmacotherapy of ADD. In a report by the

BEHAVES MORE NATURALLY.

National Council on Child Health,[1] Ritalin was described as among the most effective and best-documented agents for stimulant therapy in hyperkinetic children.

Reduces hyperactivity, impulsive behavior

Ritalin has a well-documented record of success in relieving the dominant symptoms of ADD. As it reduces distractibility, disorganized behavior and hyperactivity, improved school performance usually results,[2,3] as well as better peer interaction.[2]

Generally well tolerated

Although side effects may occur with Ritalin, they are generally not serious. During prolonged therapy, anorexia, weight loss, and insomnia are among the most frequently encountered adverse reactions. (See Adverse Reactions section of the prescribing information.) Even though most children require long-term treatment, there is little evidence of habituation.[1]

Therapy with Ritalin should be considered only after a medical diagnosis of ADD has been confirmed. Dosage can usually be interrupted during weekends and vacations. In some cases, these drug holidays reveal "stabilization" in the child's behavior without medication. They may permit a reduction in dosage and eventual discontinuation of drug therapy if warranted.

*Attention Deficit Disorders: new designation by the American Psychiatric Association; formerly called Minimal Brain Dysfunction (MBD) or Hyperkinetic Syndrome.

TABLETS

INDICATIONS

Attention Deficit Disorders (previously known as Minimal Brain Dysfunction in Children). Other terms being used to describe the behavioral syndrome below include: Hyperkinetic Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, Minor Cerebral Dysfunction.

Ritalin is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate-to-severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Special Diagnostic Considerations

Specific etiology of this syndrome is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate-to-severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with this syndrome. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin. Clinical experience suggests that in psychotic children, administration of Ritalin may exacerbate symptoms of behavior disturbance and thought disorder.

Ritalin should not be used for the prevention or treatment of normal fatigue states.

There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.

Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

Drug treatment is not indicated in all cases of this behavioral syndrome and should be considered only in light of the complete history and evaluation of the child. The decision to prescribe Ritalin should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with Ritalin is usually not indicated.

Long-term effects of Ritalin in children have not been well established.

The Ritalin tablets (5 and 20 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

Dispense in tight, light-resistant container (USP).

665382 C80-14 (1/80)

Consult complete product literature before prescribing.

Instrumentation Laboratory announces the second in a series of timely symposia on The Function of Red Blood Cells...

Erythrocyte Pathobiology

A group of internationally renowned physicians and scientists will comprise the symposium faculty:

R.M. Babior, M.D.
R.W. Briehl, M.D.
H.F. Bunn, M.D.
R.J. Cherry, Ph.D.
J.W. Eaton, Ph.D.
I. Fridovitch, Ph.D.
H.S. Jacob, M.D.
E.R. Jaffe, M.D.
P.F. Milner, M.D.
M. Morrison, Ph.D.
R.L. Nagel, M.D.
J. Palek, M.D.
H. Passow, Ph.D.
H.M. Ranney, M.D.
A. Rothstein, Ph.D.
S.B. Shohet, M.D.
H.S. Urbanetti, M.D.
D.F.H. Wallach, M.D.

When/Where
Mon., Tues., Wed., April 21-23, 1980
The Marriott Hotel, Boston (Newton), MA

Subject Matter
Presentations will focus on erythrocyte disorders, with emphasis on: genetically and functionally abnormal hemoglobins, disorders of the erythrocyte membrane and cytoskeleton, susceptibility of erythrocytes to toxic agents (such as lead and mercury) and instrumental aspects of diagnosis.

State-of-the-art research findings and their clinical significance will be emphasized. Ample time will be allotted for discussion and questions.

Accreditation
Participants may receive accreditation from Tufts University School of Medicine (17 credit hours, Category I, A.M.A. Physician's Recognition Award).

How to Register
Early registration is suggested since admission will be on a first come, first serve basis. The fee for the symposium is $295 ($50 for residents, interns and students). Make checks payable to BLOOD CELL SYMPOSIUM and send to P.O. Box 4853, Boston, MA 02212.

For further information, call IL toll-free: 800-225-4040 (800-342-8856 in MA), ext. 1215. Or write: Philip Spergel, Instrumentation Laboratory, Inc., 113 Hartwell Ave., Lexington, MA 02173.

Brief Summary

E.E.S.®

(ERYTHROMYCIN ETHYLSUCCINATE)

Indications: *Streptococcus pyogenes* (Group A beta hemolytic streptococcus)—Upper and lower respiratory tract infections, skin, and soft tissue infections of mild to moderate severity, where oral medication is preferred. Therapy should be continued for 10 days.

Alpha-hemolytic streptococci (viridans group)—Short-term prophylaxis of bacterial endocarditis prior to dental or other operative procedures in patients with a history of rheumatic fever or congenital heart disease who are hypersensitive to penicillin.

S. aureus—Acute infections of skin and soft tissue of mild to moderate severity. Resistant organisms may emerge during treatment.

S. pneumoniae (D. pneumoniae)—Upper and lower respiratory tract infections of mild to moderate degree.

M. pneumoniae—For respiratory infections due to this organism.

Hemophilus influenzae: For upper respiratory tract infections of mild to moderate severity when used concomitantly with adequate doses of sulfonamides. Not all strains of this organism are susceptible at the erythromycin concentrations ordinarily achieved (see appropriate sulfonamide labeling for prescribing information).

Treponema pallidum—As an alternate treatment in patients allergic to penicillin.

C. diphtheriae and C. minutissimum—As an adjunct to antitoxin. In the treatment of erythrasma.

Entamoeba histolytica—In the treatment of intestinal amebiasis.

L. monocytogenes—Infections due to this organism.

Legionnaires' Disease—Although no controlled clinical efficacy studies have been conducted, *in vitro* and limited preliminary clinical data suggest that erythromycin may be effective in treating Legionnaires' Disease.

Establish susceptibility of pathogens to erythromycin, particularly when *S. aureus* is isolated.

Contraindications: Known hypersensitivity to erythromycin.

Warnings: Safety for use in pregnancy has not been established.

Precautions: Exercise caution in administering to patients with impaired hepatic function. There have been reports of hepatic dysfunction, with or without jaundice, occurring in patients receiving oral erythromycin products. Recent data from studies of erythromycin reveal that its use in patients who are receiving high doses of theophylline may be associated with an increase of serum theophylline levels and potential theophylline toxicity. In cases of theophylline toxicity and/or elevated serum theophylline levels the dose of theophylline should be reduced while the patient is receiving concomitant erythromycin therapy. Surgical procedures should be performed when indicated.

Adverse Reactions: Dose-related abdominal cramping and discomfort. Nausea, vomiting, and diarrhea infrequently occur. During prolonged or repeated therapy, there is a possibility of overgrowth of nonsusceptible bacteria or fungi. Mild allergic reactions such as urticaria and other skin rashes may occur. Serious allergic reactions, including anaphylaxis, have been reported.

ABBOTT

"He was allergic to cow's milk. And soy milk. So our doctor prescribes Meyenberg Goat Milk."

Because there is no substitute for real milk.

Since the offending antigen in cow's milk is usually lactalbumin, a specific protein, Meyenberg Goat Milk has frequently proven a practical and successful substitute for cow's milk. Goat milk does not deprive the infant of the important and irreplaceable values of milk, such as occurs when synthetic milk formulas are used.

Meyenberg Goat Milk is nutritionally equal to cow's milk in protein, carbohydrate, and fat. It contains no crude fibers or other extraneous materials which cause digestive upset.

Available in Evaporated and Powdered form. Send the enclosed coupon for further information and a full-size can. Meyenberg™ BRAND

Yes, please ☐ send a free sample.

Return this coupon and we'll send you a full-size can of evaporated goat milk by return mail.

AMA AMERICAN MEDICAL ASSOCIATION

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY

OTITIS MEDIA (ACUTE): AURALGAN is indicated for relief of pain and reduction of inflammation in the congestive and serous stages of acute otitis media. It is effective adjuvant therapy when antibiotics or sulfonamides are administered systemically.

Administration: Otitis media (acute): Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching ear with dropper. Then, moisten cotton pledget with AURALGAN and insert into the meatus. Repeat every one to two hours (or three or four times a day).

REMOVAL OF CERUMEN: AURALGAN facilitates the removal of excessive or impacted cerumen.

Administration for Removal of Cerumen: Instill AURALGAN three times daily for two days to help detach cerumen from wall of canal and facilitate removal of plug. Irrigate with warm water.

Note: Keep well closed. Do not rinse dropper after use.

SUPPLIED: No. 1000—AURALGAN Otic Solution, in package containing 15 ml (1/2 fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY.
ON PRESCRIPTION ONLY.

Have you ruled out cow-milk sensitivity?

The physical symptoms are many and varied: diarrhea, colic, eczema, asthma, vomiting, bronchitis, rhinitis. They can be coupled with behavioral symptoms: repeated refusal of the nursing bottle . . . general fussiness.[1-3]

Alone or together, the manifestations of milk sensitivity are an unnecessary burden for the infant . . . and parents. More important, if unchecked the allergic syndromes can lead to failure to thrive and other serious health problems.[4]

With Isomil® Soy Protein Formula you can avoid the symptoms of milk sensitivity and help confirm your initial diagnosis.

Moreover, Isomil promotes normal growth.[2,5] It looks like milk, it pours like milk and has a pleasant aroma, which help insure acceptability. Unlike milk, Isomil is lactose free. It avoids the possibility of prolonged or recurring diarrhea caused by lactose intolerance.

Consider the possibility of milk sensitivity when associated symptoms are presented. "A high index of suspicion" is essential to its prompt detection.[2,6]

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

Subscription Rates: The yearly rates for the AMERICAN JOURNAL OF DISEASES OF CHILDREN is as follows: for members of the AMA, $1.50, included in the annual membership dues; for non-members, $24 for one year, $40 for two years in the United States and US possessions; all other countries, $34 for one year, $60 for two years. Special yearly price to residents, interns, and medical students in the United States and US possessions, one year, $12; two years, $20. Address all subscription communications to Circulation-Fulfillment Department. Phone: 312, 751-6079.

Change of Address: POSTMASTER, send address changes to Helen R. Mazur, Director, Circulation-Fulfillment. Notification of address changes should be sent at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AMERICAN JOURNAL OF DISEASES OF CHILDREN (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

ACTIFED-C® Expectorant Ⓥ

Each 5 cc teaspoonful contains: codeine phosphate 10 mg (Warning—may be habit-forming); Actidil® brand triprolidine HCl 2 mg; Sudafed® brand pseudoephedrine HCl 30 mg; guaifenesin 100 mg. Preservatives are methylparaben 0.1% and sodium benzoate 0.1%.

With the cough-stopping power of codeine.

Controls Excessive Coughing Without Preventing Productive Expectoration

Persistent, repetitive, dry coughs can be a problem in the pediatric patient, particularly at night when it often disturbs sleep. Actifed-C is made for this type of cough.

It contains codeine to reduce severity and persistence plus guaifenesin to liquefy and ease the expulsion of mucus. Moreover, Actifed-C is the only cough medication that contains triprolidine and pseudoephedrine... the decongestant/antihistamine combination that has been part of the NASA Space Medicine Kit since 1968.

Indications: Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Lacking substantial evidence of effectiveness as a fixed combination": For the symptomatic relief of cough in conditions such as: the common cold, acute bronchitis, allergic asthma, bronchiolitis, croup, emphysema, tracheobronchitis.

Final classification of the less-than-effective indications requires further investigation.

Warning: Use in Pregnancy: Experience with this drug in pregnant women is inadequate to determine whether there exists a potential for harm to the developing fetus.

Precautions: Although pseudoephedrine hydrochloride causes virtually no pressor effect in normotensive patients, it should be used with caution in patients with hypertension. In addition, even though triprolidine hydrochloride produces only a low incidence of drowsiness, appropriate precautions should be observed.

Side Effects: The great majority of patients will not have any side effects. Only certain patients, sensitive to one or another of the ingredients, may note mild stimulation or mild sedation.

Supplied: Bottles of 1 pint. Complete literature available on request from Professional Services Dept. PML.

Not recommended for use in children under 2 years of age.

ONE HUNDRED YEARS WELLCOME

Burroughs Wellcome Co.

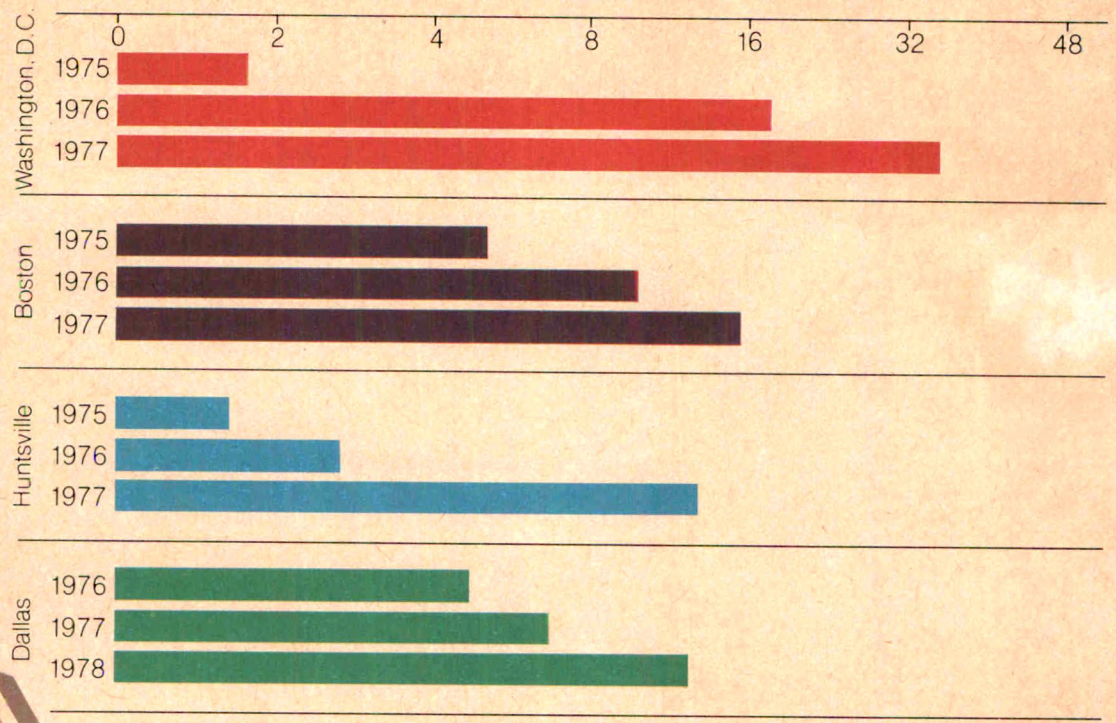
Increasing resistance o



Brief Summary.
Consult the package literature for prescribing information.

Indications and Usage: Ceclor®(cefaclor, Lilly) is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms:

Otitis media caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci).

Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor.

Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PENICILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS TO BOTH DRUG CLASSES (INCLUDING ANAPHYLAXIS AFTER PARENTERAL USE)

Antibiotics, including Ceclor® (cefaclor, Lilly), should be administered cautiously to any patient who has demonstrated some form of allergy, particularly to drugs.

Precautions: If an allergic reaction to cefaclor occurs, the drug should be discontinued, and, if necessary, the patient should be treated with appropriate agents, e.g., pressor amines, antihistamines, or corticosteroids.

Prolonged use of cefaclor may result in the overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Positive direct Coombs tests have been reported during treatment with the cephalosporin antibiotics. In hematologic studies or in transfusion cross-matching procedures when antiglobulin tests are performed on the minor side in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it

Haemophilus influenzae in otitis media...

a valid concern

In many areas of the country, increasing numbers of *H. influenzae* show resistance to conventional antibiotic therapy.[1-3]

Ceclor is effective in the treatment of otitis media,† including that due to ampicillin-resistant strains of *H. influenzae*.[4-9]

Ceclor has been shown to be clinically and bacteriologically effective in treating otitis media due to susceptible organisms.[10]

Ceclor is available in two pleasant-tasting liquids.

Ceclor provides effective single-agent antibiotic therapy for otitis media.

Note: Ceclor is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

† Due to susceptible strains of *Streptococcus pneumoniae*, *H. influenzae*, staphylococci, and *S. pyogenes*.

125-mg/5-ml and 250-mg/5-ml oral suspensions

Ceclor®

cefaclor

should be recognized that a positive Coombs test may be due to the drug.

Ceclor ® (cefaclor, Lilly) should be administered with caution in the presence of markedly impaired renal function. Under such a condition, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended.

Usage in Pregnancy—Although no teratogenic or antifertility effects were seen in reproduction studies in mice and rats receiving up to 12 times the maximum human dose or in ferrets given three times the maximum human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

Usage in Infancy—Safety of this product for use in infants less than one month of age has not been established.

Adverse Reactions: In clinical studies in 1493 patients, adverse effects considered related to cefaclor therapy were uncommon and are listed below:

Gastrointestinal symptoms occurred in about 2.5 percent of patients and included diarrhea (1 in 70) and nausea and vomiting (1 in 90).

Hypersensitivity reactions were reported in about 1.5 percent of patients and included morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs tests each occurred in less than 1 in 200 patients.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain—Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic—Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic—Transient fluctuations in leukocyte count; predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal—Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

Finally going for a license...

a better life with Depakene®
Valproic Acid

For your patients with mixed seizures including absence, or pure absence

More than just effective seizure control[1]

In 28 studies of patients with mixed grand mal and absence, 76% of all patients gained significant improvement; over one-third became seizure-free. In 60 studies involving pure absence, 86% of patients were improved; half became seizure-free.

Freedom from social stigmata is important too

With Depakene, social function is unimpeded by drug-induced hirsutism or gingival hyperplasia. Intellectual function may improve as more sedative drugs are reduced in dosage or withdrawn. Patients may be able to lead a more normal life with Depakene than was possible with their previous drug regimen.

A widely useful anticonvulsant

Depakene is indicated as sole or adjunctive therapy in both simple and complex absence seizures. It is also indicated for adjunctive treatment of patients with multiple seizure types which include absence. Clinical response has been especially noteworthy among patients with generalized tonic-clonic attacks, or with minor motor seizures (e.g., myoclonic movements, akinetic seizures), where combined with absence.

Offering your patients a chance for a better life

Sustained freedom from seizures can mean a drivers license, an active social schedule, involvement in athletic competition—a better life for your patient. Depakene has not been associated with hirsutism or gingival hyperplasia. Sedation has not been a frequent problem. The most common side effect with Depakene is G.I. upset, which usually responds to temporary dosage reduction. Serious side effects, including fatal hepatitis, have occurred.

1. Worldwide studies of Depakene experience (Data refer only to grand mal and/or absence seizures. Since each type was evaluated separately, some patients appear in both groups. Though most of these studies were uncontrolled and had widely differing protocols, their collective data clearly support efficacy of the drug).

See overleaf for brief summary of prescribing information

Abbott Laboratories,
North Chicago, Illinois 60064

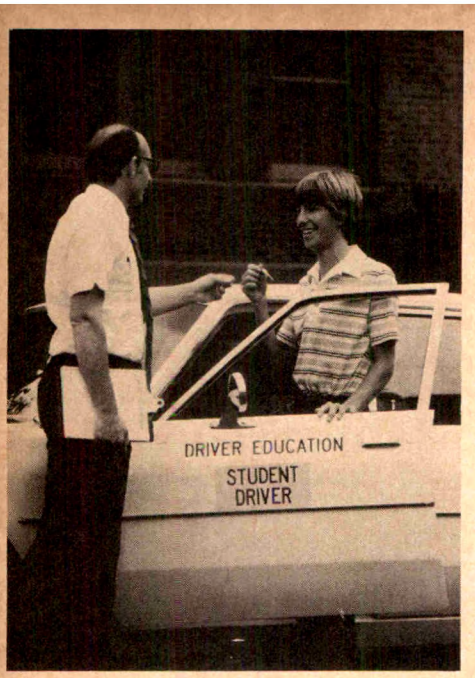
Offering a chance for a better life
for your patients with mixed seizures including absence, or pure absence

Depakene®
Valproic Acid



Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

A BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS: DEPAKENE (valproic acid) is indicated for use as sole and adjunctive therapy in the treatment of simple and complex absence seizures, including petit mal. DEPAKENE may also be used adjunctively in patients with multiple seizure types which include absence seizures.

In accordance with the International Classification of Seizures, simple absence is defined as very brief clouding of the sensorium or loss of consciousness (lasting usually 2-15 seconds), accompanied by certain generalized epileptic discharges without other detectable clinical signs. Complex absence is the term used when other signs are also present.

CONTRAINDICATIONS: DEPAKENE (valproic acid) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: Hepatic failure resulting in fatalities has occurred in patients receiving DEPAKENE. These incidences usually have occurred during the first six months of treatment with DEPAKENE. Liver function tests should be performed prior to therapy and at frequent intervals thereafter. Caution should be observed when administering DEPAKENE to patients with pre-existing hepatic disease.

The drug should be discontinued immediately in the presence of significant hepatic dysfunction, suspected or apparent. The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing the dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher dosages.

Usage in Pregnancy: THE EFFECTS OF DEPAKENE IN HUMAN PREGNANCY ARE UNKNOWN. ANIMAL STUDIES HAVE DEMONSTRATED TERATOGENICITY.

Studies in rats demonstrated placental transfer of the drug. Doses greater than 65 mg/kg/day given to pregnant rats and mice produced skeletal abnormalities in the offspring, primarily involving ribs and vertebrae; doses greater than 150 mg/kg/day given to pregnant rabbits produced fetal resorptions and (primarily) soft-tissue abnormalities in the offspring. In rats a dose-related delay in the onset of parturition was noted. Postnatal growth and survival of the progeny were adversely affected, particularly when drug administration spanned the entire gestation and early lactation period.

THERE ARE MULTIPLE REPORTS IN THE CLINICAL LITERATURE WHICH INDICATE THAT THE USE OF ANTICONVULSANT DRUGS DURING PREGNANCY RESULTS IN AN INCREASED INCIDENCE OF BIRTH DEFECTS IN THE OFFSPRING. ALTHOUGH DATA ARE MORE EXTENSIVE WITH RESPECT TO TRIMETHADIONE, PARAMETHADIONE, PHENYTOIN, AND PHENOBARBITAL, REPORTS INDICATE A POSSIBLE SIMILAR ASSOCIATION WITH THE USE OF OTHER ANTICONVULSANT DRUGS. THEREFORE, ANTICONVULSANT DRUGS SHOULD BE ADMINISTERED TO WOMEN OF CHILDBEARING POTENTIAL ONLY IF THEY ARE CLEARLY SHOWN TO BE ESSENTIAL IN THE MANAGEMENT OF THEIR SEIZURES.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

PRECAUTIONS: *Hepatic dysfunction:* See WARNINGS.

General: Because of reports of thrombocytopenia and platelet aggregation dysfunction, platelet counts and bleeding time determination are recommended before initiating therapy and at periodic intervals. It is recommended that patients receiving DEPAKENE be monitored for platelet count prior to planned surgery. Clinical evidence of hemorrhage, bruising or a disorder of hemostasis/coagulation is an indication for reduction of DEPAKENE dosage or withdrawal of therapy pending investigation.

Since DEPAKENE (valproic acid) may interact with concurrently administered anticonvulsant drugs, periodic serum level determinations of concomitant anticonvulsant drugs are recommended during the early course of therapy. (See Drug Interactions).

DEPAKENE is partially eliminated in the urine as a keto-metabolite which may lead to a false interpretation of the urine ketone test.

Information For Patients: Since DEPAKENE may produce CNS depression, especially when combined with another CNS depressant (e.g., alcohol), patients should be advised not to engage in hazardous occupations, such as driving an automobile or operating dangerous machinery, until it is known that they do not become drowsy from the drug.

Drug Interactions: DEPAKENE may potentiate the CNS depressant activity of alcohol.

THERE IS EVIDENCE THAT DEPAKENE MAY CAUSE AN INCREASE IN SERUM PHENOBARBITAL LEVELS, ALTHOUGH THE MECHANISM OF THE INTERACTION IS UNKNOWN. ALL PATIENTS RECEIVING CONCOMITANT BARBITURATE THERAPY SHOULD BE CLOSELY MONITORED FOR NEUROLOGICAL TOXICITY, SERUM BARBITURATE DRUG LEVELS OBTAINED, IF POSSIBLE, AND THE BARBITURATE DOSAGE DECREASED, IF APPROPRIATE.

Primidone is metabolized into a barbiturate and, therefore, may also be involved in a similar or identical interaction.

THERE IS CONFLICTING EVIDENCE REGARDING THE INTERACTION OF DEPAKENE WITH PHENYTOIN. IT IS NOT KNOWN IF THERE IS A CHANGE IN UNBOUND (FREE) PHENYTOIN SERUM CONCENTRATIONS. THE DOSAGE OF PHENYTOIN SHOULD BE ADJUSTED AS REQUIRED BY THE CLINICAL SITUATION.

THE CONCOMITANT USE OF VALPROIC ACID AND CLONAZEPAM MAY PRODUCE ABSENCE STATUS.

Caution is recommended when DEPAKENE (valproic acid) is administered with drugs affecting coagulation, e.g., aspirin and warfarin. (See ADVERSE REACTIONS).

Carcinogenesis, Mutagenesis: There has been insufficient study of the drug in animals to determine whether it has carcinogenic potential. Carcinogenicity studies in rats and mice are currently in progress.

Mutagenesis studies on DEPAKENE have been performed using bacterial and mammalian systems. These studies have provided no evidence of a mutagenic potential for DEPAKENE.

Pregnancy: See WARNINGS.

Nursing Mothers: DEPAKENE is excreted in breast milk. It is not known what effect this would have on a nursing infant. As a general rule, nursing should not be undertaken while a patient is receiving DEPAKENE.

Fertility: Chronic toxicity studies in juvenile and adult rats and dogs demonstrated reduced spermatogenesis and testicular atrophy at doses greater than 200 mg/kg/day in rats and greater than 90 mg/kg/day in dogs. Segment I fertility studies in rats have shown doses up to 350 mg/kg/day for 60 days to have no effect on fertility. THE EFFECT OF DEPAKENE (VALPROIC ACID) ON THE DEVELOPMENT OF THE TESTES AND ON SPERM PRODUCTION AND FERTILITY IN HUMANS IS UNKNOWN.

ADVERSE REACTIONS: Since DEPAKENE (valproic acid) has usually been used with other anticonvulsant drugs, it is not possible, in most cases, to determine whether the following adverse reactions can be ascribed to DEPAKENE alone, or the combination of drugs.

Gastrointestinal: The most commonly reported side effects at the initiation of therapy are nausea, vomiting and indigestion. These effects are usually transient and rarely require discontinuation of therapy. Diarrhea, abdominal cramps and constipation have been reported. Both anorexia with some weight loss and increased appetite with weight gain have also been reported.

CNS Effects: Sedative effects have been noted in patients receiving valproic acid alone but are found most often in patients receiving combination therapy. Sedation usually disappears upon reduction of other anticonvulsant medication. Ataxia, headache, nystagmus, diplopia, asterixis, "spots before eyes", tremor, dysarthria, dizziness, and incoordination have rarely been noted. Rare cases of coma have been noted in patients also on phenobarbital.

Dermatologic: Transient increases in hair loss have been observed. Skin rash and petechiae have rarely been noted.

Psychiatric: Emotional upset, depression, psychosis, aggression, hyperactivity and behavioral deterioration have been reported.

Musculoskeletal: Weakness has been reported.

Hematopoietic: Thrombocytopenia has been reported. Valproic acid inhibits the secondary phase of platelet aggregation. (See DRUG INTERACTIONS). This may be reflected in altered bleeding time. Bruising, hematoma formation and frank hemorrhage have been reported. Relative lymphocytosis and hypofibrinogenemia have been noted. Leukopenia and eosinophilia have also been reported.

Hepatic: Increases in serum alkaline phosphatase and elevations of serum glutamic oxaloacetic transaminase (SGOT) have been noted. Elevation of SGOT may be dose related. Elevations of SGPT and LDH have been noted less frequently. Isolated cases of severe hepatotoxicity have been reported but do not appear dose related. (See WARNINGS).

OVERDOSAGE: A single case of overdosage with valproic acid has been reported. After ingesting 36 grams in combination with phenobarbital and phenytoin, the patient presented in deep coma. An electroencephalogram recorded diffuse slowing, compatible with the state of consciousness. The patient made an uneventful recovery.

Since DEPAKENE is absorbed very rapidly, gastric lavage may be of limited value. General supportive measures should be applied with particular attention being given to the maintenance of adequate urinary output.

DOSAGE AND ADMINISTRATION: DEPAKENE (valproic acid) is administered orally. The recommended initial dose is 15 mg/kg/day, increasing at one week intervals by 5 to 10 mg/kg/day, until seizures are controlled or side effects preclude further increases. The maximum recommended dosage is 60 mg/kg/day. If the total daily dose exceeds 250 mg, it should be given in a divided regimen.

The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increased dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher doses.

The following table is a guide for the initial daily dose of DEPAKENE (valproic acid) (15 mg/kg/day):

Weight (kg)	Weight (lb)	Total Daily Dose (mg)	Number of Capsules or Teaspoonfuls of Syrup Dose 1	Dose 2	Dose 3
10 - 24.9	22 - 54.9	250	0	0	1
25 - 39.9	55 - 87.9	500	1	0	1
40 - 59.9	88 - 131.9	750	1	1	1
60 - 74.9	132 - 164.9	1,000	1	1	2
75 - 89.9	165 - 197.9	1,250	2	1	2

A good correlation has not been established between daily dose, serum level and therapeutic effect, however, therapeutic serum levels for most patients will range from 50 to 100 mcg/ml. Occasional patients may be controlled with serum levels lower or higher than this range.

As the DEPAKENE dosage is titrated upward, blood levels of phenobarbital and/or phenytoin may be affected. (See PRECAUTIONS).

Patients who experience G.I. irritation may benefit from administration of the drug with food or by slowly building up the dose from an initial low level.

THE CAPSULES SHOULD BE SWALLOWED WITHOUT CHEWING TO AVOID LOCAL IRRITATION OF THE MOUTH AND THROAT.

HOW SUPPLIED: DEPAKENE (valproic acid) is available as orange-colored soft gelatin capsules of 250 mg valproic acid in bottles of 100 capsules (**NDC** 0074-5681-13), and as a red syrup containing the equivalent of 250 mg valproic acid per 5 ml as the sodium salt in bottles of 16 ounces (**NDC** 0074-5682-16).

NOW PETER

Attention Deficit Disorders* under control...
His natural abilities are coming through

Now Peter's enjoying more things at play as well as in school. He works better with his teacher and classmates... likes doing things with his dad... gets more natural pleasure out of family and friends.

Now that his concentration is improved, his natural abilities are coming through. He's functioning better. Under a well-integrated program of treatment for Attention Deficit Disorders (ADD), hyperactivity and impulsiveness are markedly reduced.

Ritalin (methylphenidate) can be a vital part of his regimen. With adjunctive use of Ritalin, many ADD children are better able to control hyperkinetic behavior —act in a more natural and appropriate manner.

A 20-year record of proven efficacy

Over the years, Ritalin has become an established choice for pharmacotherapy of ADD. In a report by the

BEHAVES MORE NATURALLY.

National Council on Child Health,[1] Ritalin was described as among the most effective and best-documented agents for stimulant therapy in hyperkinetic children.

Reduces hyperactivity, impulsive behavior

Ritalin has a well-documented record of success in relieving the dominant symptoms of ADD. As it reduces distractibility, disorganized behavior and hyperactivity, improved school performance usually results,[2,3] as well as better peer interaction.[2]

Generally well tolerated

Although side effects may occur with Ritalin, they are generally not serious. During prolonged therapy, anorexia, weight loss, and insomnia are among the most frequently encountered adverse reactions. (See Adverse Reactions section of the prescribing information.) Even though most children require long-term treatment, there is little evidence of habituation.[1]

Therapy with Ritalin should be considered only after a medical diagnosis of ADD has been confirmed. Dosage can usually be interrupted during weekends and vacations. In some cases, these drug holidays reveal "stabilization" in the child's behavior without medication. They may permit a reduction in dosage and eventual discontinuation of drug therapy if warranted.

***Attention Deficit Disorders:** new designation by the American Psychiatric Association; formerly called Minimal Brain Dysfunction (MBD) or Hyperkinetic Syndrome.

Ritalin . . . only when medication is indicated for Attention Deficit Disorders

Please turn page for brief prescribing information.

Ritalin® C II (methylphenidate)

Only when medication is indicated

Ritalin® hydrochloride (methylphenidate hydrochloride USP) C II

TABLETS

INDICATIONS

Attention Deficit Disorders (previously known as Minimal Brain Dysfunction in Children). Other terms being used to describe the behavioral syndrome below include: Hyperkinetic Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, Minor Cerebral Dysfunction.

Ritalin is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate-to-severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Special Diagnostic Considerations

Specific etiology of this syndrome is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate-to-severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with this syndrome. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin. Clinical experience suggests that in psychotic children, administration of Ritalin may exacerbate symptoms of behavior disturbance and thought disorder.

Ritalin should not be used for the prevention or treatment of normal fatigue states.

There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.

Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

Drug treatment is not indicated in all cases of this behavioral syndrome and should be considered only in light of the complete history and evaluation of the child. The decision to prescribe Ritalin should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with Ritalin is usually not indicated.

Long-term effects of Ritalin in children have not been well established.

The Ritalin tablets (5 and 20 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

Dispense in tight, light-resistant container (USP).

Expressly for kids with colds that cough*

orange-pineapple flavored

Tuss-Ornade® cough/cold liquid

Each 5 ml. teaspoonful contains 5 mg. caramiphen edisylate; 2 mg. chlorpheniramine maleate; 15 mg. phenylpropanolamine hydrochloride; isopropamide iodide equivalent to 0.75 mg. of isopropamide; and alcohol, 7.5%.

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

* **Indications**

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Lacking in substantial evidence of effectiveness as a fixed combination: For relief from coughing, upper respiratory congestion and hypersecretion associated with the common cold, sinusitis, vasomotor rhinitis and allergic rhinitis.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Hypersensitivity to any component; concurrent MAO inhibitor therapy; severe hypertension; bronchial asthma; coronary artery disease; stenosing peptic ulcer; pyloroduodenal or bladder neck obstruction. Do not use 'Tuss-Ornade' Liquid in children less than six months of age or under 15 lbs. in weight. Do not use 'Tuss-Ornade' *Spansule* capsules in children under 12 years of age.

Warnings: Warn vehicle or machine operators of possible drowsiness. Warn patients of possible additive effects of alcohol and other C.N.S. depressants.

Usage in Pregnancy: Use in pregnancy, nursing mothers and women who might bear children only when potential benefits have been weighed against possible hazards. An inhibitory effect on lactation may occur.

Effect on PBI Determination and I^{131} Uptake: The iodine in isopropamide iodide may alter PBI test results and will suppress I^{131} uptake; use thyroid tests unaffected by exogenous iodides.

Precautions: Use with caution in persons with cardiovascular disease, glaucoma, prostatic hypertrophy, hyperthyroidism.

Adverse Reactions: Drowsiness; excessive dryness of nose, throat or mouth; nervousness, insomnia; nausea, vomiting, diarrhea; rash; dizziness; weakness; tightness of chest; angina pain; abdominal pain; irritability; palpitation; headache; incoordination; tremor; difficulty in urination; thrombocytopenia, leukopenia; convulsions; hypertension, hypotension; anorexia; constipation; visual disturbances; iodine toxicity (acne, parotitis); dysuria; epigastric distress.

Supplied: 'Tuss-Ornade' Liquid: An orange-pineapple flavored liquid in 16 fl. oz. bottles. For patients 12 years or older, 'Tuss-Ornade' *Spansule* capsules (each capsule contains 20 mg. caramiphen edisylate; 8 mg. chlorpheniramine maleate; 50 mg. phenylpropanolamine HCl; and isopropamide iodide equivalent to 2.5 mg. of isopropamide), in bottles of 50 and 500 capsules.

Instructions for Authors

General Information.—Send manuscripts by first-class (**not** registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation

All the elements of a manuscript should be submitted in **triplicate, double-spaced throughout.** Use heavy-duty white bond paper, 22 × 28-cm, and 4-cm margins. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda

Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor

Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References

These must be listed in order of their appearance in the text, and typed double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 131:295-296, 1977.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons Inc, 1965, pp 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders Co, 1974, pp 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations

Submit in triplicate, unmounted, and untrimmed. Send only high contrast glossy prints (not photocopies or original artwork); preferred size 12.5 × 18-cm. Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

CYCLAPEN®

(cyclacillin) Tablets/ Suspension

Usual children's dosage: 50 to 100 mg/kg/day in equally space doses, depending on severity.

more than just spectrum in otitis media, bronchitis, pneumonia, and upper respiratory tract infections*

- Rapid, virtually complete absorption from GI tract
- Rapid onset of action—mean peak serum levels within 30 minutes
- Exceptionally high peak blood levels—3 times greater than ampicillin (clinical efficacy may not always correlate with blood levels)
- Rapidly excreted unchanged in the urine—1½ times faster than ampicillin
- Significantly fewer episodes of diarrhea and skin rash than reported with ampicillin in studies to date
- Excellent clinical response and outstanding bacterial eradication documented in double-blind studies involving 2,581 patients
- New CYCLAPEN® Suspension—great-tasting raspberry punch flavor

*Due to susceptible organisms.

How Supplied

CYCLAPEN® (cyclacillin) tablets:
250 mg scored tablets
500 mg scored tablets

Indications

Cyclapen® (cyclacillin) has less in vitro activity than other drugs in the ampicillin class of antibiotics and its use should be confined to the indications listed below.

Cyclapen® is indicated for the treatment of the following infections:

RESPIRATORY TRACT

Tonsillitis and pharyngitis caused by Group A beta-hemolytic streptococci

Bronchitis and pneumonia caused by *S. pneumoniae* (formerly *D. pneumoniae*)

Otitis Media caused by *S. pneumoniae* (formerly *D. pneumoniae*) and *H. influenzae*

Acute exacerbation of chronic bronchitis caused by *H. influenzae**

*Though clinical improvement has been shown, bacteriologic cures cannot be expected in all patients with chronic respiratory disease due to *H. influenzae*.

SKIN AND SKIN STRUCTURES (integumentary) infections caused by Group A beta-hemolytic streptococci and staphylococci, non-penicillinase producers.

URINARY TRACT INFECTIONS caused by *E. coli* and *P. mirabilis*. (This drug should not be used in any infections caused by *E. coli* and *P. mirabilis* other than urinary tract infections.)

NOTE: Cultures and susceptibility tests should be performed initially and during treatment to monitor the effectiveness of therapy and the susceptibility of bacteria. Therapy may be instituted prior to the results of sensitivity testing.

Contraindications

The use of this drug is contraindicated in individuals with a history of an allergic reaction to penicillins.

Warnings

CYCLACILLIN SHOULD ONLY BE PRESCRIBED FOR THE INDICATIONS LISTED IN THIS INSERT.

CYCLACILLIN HAS LESS *IN VITRO* ACTIVITY THAN OTHER DRUGS OF THE AMPICILLIN CLASS ANTIBIOTICS. HOWEVER, CLINICAL TRIALS HAVE DEMONSTRATED THAT IT IS EFFICACIOUS FOR THE RECOMMENDED INDICATIONS.

SERIOUS AND OCCASIONAL FATAL HYPERSENSITIVITY (ANAPHYLACTOID) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING PENICILLIN.

ALTHOUGH ANAPHYLAXIS IS MORE FREQUENT FOLLOWING PARENTERAL ADMINISTRATION, IT HAS OCCURRED IN PATIENTS ON ORAL PENICILLINS. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS. THERE ARE REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY REACTIONS WHO EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH A CEPHALOSPORIN. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE ABOUT PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, THE DRUG SHOULD BE DISCONTINUED AND APPROPRIATE THERAPY SHOULD BE INITIATED. SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE, OXYGEN, INTRAVENOUS STEROIDS, AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

Precautions

Prolonged use of antibiotics may promote the overgrowth of nonsusceptible organisms. If superinfection occurs during therapy, appropriate measures should be taken.

PREGNANCY: Pregnancy Category B. Reproduction studies have been performed in mice and rats at doses up to ten times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cyclacillin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

NURSING MOTHERS: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when cyclacillin is administered to a nursing woman.

Adverse Reactions

The oral administration of cyclacillin is generally well tolerated.

As with other penicillins, untoward reactions of the sensitivity phenomena are likely to occur, particularly in individuals who have previously demonstrated

CYCLAPEN® (cyclacillin) fc
oral suspension
125 mg per 5 ml:
100 ml and 200 ml bottles
250 mg per 5 ml:
100 ml and 200 ml bottles

hypersensitivity to **penicillins** or in those with a history of allergy, ast fever, or urticaria.

The following adverse reactions have been reported with the use of c diarrhea (in approximately 1 out of 20 patients treated), nausea and (in approximately 1 in 50), and skin rash (in approxrmately 1 in 60) instances of headache, dizziness, abdominal pain, vaginitis, and urtic been reported. (See WARNINGS)

Other less frequent adverse reactions which may occur and that h reported during therapy with other penicillins are: anemia, thromboc thrombocytopenic purpura, leukopenia, neutropenia and eosinophili reactions are usually reversible on discontinuation of therapy.

As with other semisynthetic penicillins, SGOT elevations have been r

Dosage and Administration

INFECTION*	ADULTS	CHILDREN
		Dosage should n in a dose higher t for adults.
Respiratory Tract		
Tonsillitis & Pharyngitis**	250 mg q.i.d. in equally spaced doses	body weight <2(lbs) 125 mg q equally spaced d body weight >2(lbs) 250 mg q equally spaced d
Bronchitis and Pneumonia		
Mild or Moderate Infections	250 mg q.i.d. in equally spaced doses	50 mg/kg/day (equally spaced d
Chronic Infections	500 mg q.i.d. in equally spaced doses	100 mg/kg/day equally spaced d
Otitis Media	250 mg to 500 mg q.i.d. in equally spaced doses depending on severity	50 to 100 mg/k equally spaced d pending on severi
Skin & Skin Structures	250 mg to 500 mg q.i.d. in equally spaced doses depending on severity	50 to 100 mg/k equally spaced d pending on severi
Urinary Tract	500 mg q.i.d. in equally spaced doses	100 mg/kg/day in spaced doses.

*As with antibiotic therapy generally, treatment should be continue minimum of 48 to 72 hours after the patient becomes asymptomatic evidence of bacterial eradication has been obtained.

**In infections caused by Group A beta-hemolytic streptococci, a mini 10 days of treatment is recommended to guard against the risk of rh fever or glomerulonephritis.

In the treatment of chronic urinary tract infection, frequent bacteriolc clinical appraisal is necessary during therapy and may be required for months afterwards.

Persistent infection may require treatment for several weeks.

Cyclacillin is not indicated in children under 2 months of age.

Patients with Renal Failure

Based on a dosage of 500 mg q.i.d., the following adjustment in interval is recommended:

Patients with a creatinine clearance of >50 ml/min need age interval adjustment.

Patients with a creatinine clearance of 30-50 ml/min should rec doses every 12 hours.

Patients with a creatinine clearance of between 15-30 ml/mir receive full doses every 18 hours.

Patients with a creatinine clearance of between 10-15 ml/mir receive full doses every 24 hours.

In patients with a creatinine clearance of ≤10 ml/r serum creatinine values of ≥ 10 mg %, serum cyclacillin levels are mended to determine both subsequent dosage and frequency.

The Many Advantages of Direct Microfocus Roentgenographic Magnification in Pediatric Radiology

A Portable X-ray Machine With a Uniquely Different X-ray Tube

Direct radiographic magnification as a means of complementing diagnostic imaging is not a new concept.[1] The technique has been used widely, but never applied generally because a "bigger" image was not necessarily a "better" image. The physics of direct roentgenographic imaging is a complex marriage of x-ray beam geometry and the physicochemistry of photon absorption within a cassette.

Until the time of development of the Radiological Sciences Inc (RSI) x-ray tube, virtually all medical x-ray tubes depended on a hot tungsten filament as the initial source of electrons for the generation of x-ray photons (ie, since 1913, when Coolidge[2] introduced the first filament x-ray tube). Detail in magnification is adversely affected by imperfections in the beam source. The standard filament x-ray tubes usually produce two point sources and a trailing edge of radiation off their axes. The resultant images are blurred, and this blurring is amplified by magnification. Therefore, the more precise the point source, the sharper the projected image.

The RSI tube uses a smooth tungsten block as an electron source. Five electron-focusing lenses in the tube produce a focal spot of about 90 μ. Although there is a small difference between microfocus (90 μ) and conventional fractional focal spots (100 μ), it is the single sharp point source that accounts for the improvement. The advent of the microfocus tube opened the way for the second essential step.

It has been shown repeatedly that the very high-speed, intensifying screen-x-ray film recording systems provide excellent roentgenographic detail when used for direct magnification.[3] Very high-speed (rare earth) systems may not provide satisfactory detail for some (nonmagnified) roentgenographic examinations.

However, the appropriate implementation of a microfocus x-ray source with a cassette containing rare earth recording material results in enlargement of the anatomic part, with better detail than is available by the techniques of standard roentgenography.

Clinical application of this new modality has not reached its full potential; however, our experience at the Cardinal Glennon Memorial Hospital for Children, St Louis, points to future applications.

FUTURE USES

Bone

Trauma.—Threefold magnification opens up a new area of early and confirmed diagnosis. For example, minimal periosteal reaction is detectable much more easily. Minute chip fractures in infant bone may not be detectable by any other means, although minute fractures can occasionally be detected by techniques such as "nonscreen" and xeroradiographs. The radiation dose is greater by a factor of about four for xeroradiography.

Scaphoid Injury.—Often, suspicion of fracture of the scaphoid requires multiple views to resolve the question. A single direct magnification projection may solve the problem. For most of us, confirming the "normal" may be just as important as showing the abnormal.

Abused Children.—Abused babies may sustain minute metaphyseal avulsion fractures as the result of violent shaking, jerking, and twisting. These findings might allow us to move through the complexities of evaluating the "suspected" battered child with greater confidence and in a much shorter time. The demonstration of such fractures are admissible as evidence in court.

Radionuclide scintigraphy may identify areas of hyperemia within a few hours after trauma. In most instances, the region already is under suspicion, so that what is needed is a definitive morphological demonstration. Magnification may be the only low-radiation technique that can detect minute fractures.

Inflammation.—The early use of antibiotics has changed the natural evolution of radiographic bone change in osteomyelitis. The earliest roentgenographic change is deep, soft-tissue edema. The use of xeroradiographic or "nonscreen" techniques is discouraged

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

because of the greater amount of radiation required. A single view, threefold magnification provides excellent soft-tissue visualization because of the contrast enhancement that is part of all such roentgenographs, and it also establishes a baseline for sequential comparisons. Minimal bone destruction or periosteal reaction may be better documented by magnification than by other techniques. Radionuclide scintigraphy may identify areas of increased uptake, but do not specify bone destruction.

Tumor.—We find increasingly that discrimination can be made between benign and malignant bone tumors. Early malignant bone change particularly lends itself to more precise evaluation. Improved resolution in bone tumor cases has encouraged operative confirmation without intervening tomographic and vascular studies (Fig 1 through 3).

Arthritis.—Used as a baseline roentgenogram, fourfold magnification of a finger is an excellent means for early identification of arthritic change and for detection of its subtle differential characteristics.

Middle Ear Disease

Structures in the base of the skull and, especially, the middle ear can be magnified with ease, allowing for visualization of the tympanum, malleus, and incus. We use the technique when indicated to complement a petromastoid examination.

Temporomandibular (TM) Joint

Conventional roentgenography of the TM joint may be an enigma to many radiologists and maxillofacial surgeons. A threefold magnification of a lateral TM joint projection may show precise cortical detail of both subchondral surfaces. Recent work by Murphy and associates[4] has greatly enhanced the usefulness of techniques for the study of TM joint abnormalities by having introduced a new positioning device.

Chest

Taking advantage of the high-speed image recording, microfocus direct roentgenographic magnification of the chest becomes a practical reality

Fig 1.—Skull roentgenogram of 10-year-old boy who had soft, fluctuant mass in scalp, with area of bone destruction near vertex (arrow).

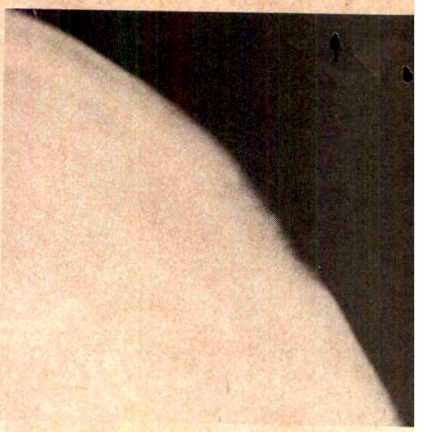

Fig 2.—Oblique threefold magnification roentgenogram of that same portion of calvaria, clearly showing destruction of outer table and intact inner table. Destruction is very irregular; some invasion into diploic space is seen.

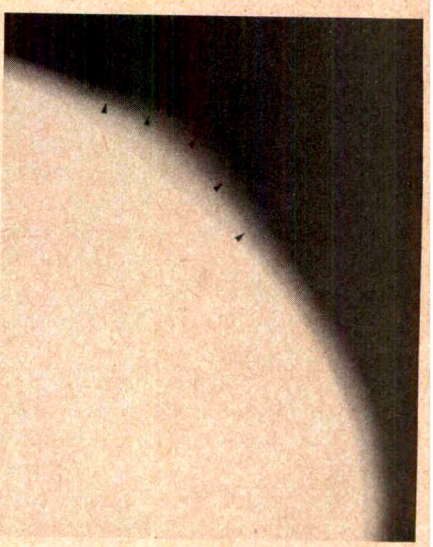
Fig 3.—Same region as shown on Fig 2, except that threefold magnification roentgenogram was made for soft tissue. Contrast enhancement afforded by magnification shows tissue planes, outline of mass in deep soft tissues (arrows), and no evidence of inflammation (edema). On basis of fact that bone is destroyed and invaded, and fact that there is no evidence of edema, diagnosis of tumor was made. Biopsy specimen confirmed osteosarcoma.



in the neonate. We are convinced that many pediatric radiologists and some neonatologists have little need for roentgenographic enhancement in the daily pursuit of their specialty. For them, magnification of the chest of a small premature infant may be unnecessary. However, for the general radiologist or the pediatrician who ponders over the changes at the base of the lung in a tiny baby, roentgenographic enlargement can be a godsend by providing improved image detail as well as roentgenographic enlargement. The subtle changes of hyaline membrane disease, of congenital heart disease, and of pulmonary interstitial emphysema are more readily appreciated with this technique.

PRACTICAL APPLICATION

First, radiologic technologists are able to manipulate routine magnification techniques with the same ease and facility as they do with standard contact radiography. Second, bone detail is of such high quality that the "additional" or "second" view in doubtful cases could be a magnified one. Depending on the initial imaging system used, the "image" may show improved bone detail. Third, the magnified chest roentgenograph defines the minutiae of pathologic change, rendering the pattern more recognizable. It is only the most experienced pediatric radiologist who does not need this technique. Finally, our initial experience with microfocus magnification applications in vascular angiography and in image amplification, spot "film" roentgenography indicates that there are very definite advantages to the radiologist. In fact, it would seem that until the advent of the RSI tube, magnification of small vessels was impractical because the

bigger image was not necessarily a better image, and because it was also more blurred.

The use of extremely high-speed rare earth screen/film recording systems is practical and effective. In our experience, the Trimax 12 (3M Company) intensifying screens, combined with X-M or X-D orthochromatic film has proved to be the fastest available system that will record in satisfactory detail. The greatest single advantage is the increased margin of confidence it provides to the daily challenge of diagnosis.

Condoms for Sexually Active Adolescents

To the individual physician, public health statistics sometimes have a way of seeming so awesome as to appear abstract and remote. In a way, the grim numbers of teenage pregnancies and sexually transmitted diseases (STDs) are reminiscent of the casualty reports from the Viet Nam War. One recognizes that something large and awful is taking place, but the problem is perceived to be so massive that any control measures attempted would have as much influence as spitting in the ocean.

Though the public at large may not appreciate the full dimensions of the teenage pregnancy problem, physicians, and especially pediatricians, cannot hide behind a shield of ignorance. Most of us have daily dealings with the offspring of children who are too young biologically and emotionally to be parents. The most obvious example is the inordinate number of low-birth-weight infants that are born to teenage mothers. Imagine the impact on the "business" of neonatal intensive care units if even a small dent were made in teenage pregnancy rates! We would also see a decrease in the number of cases of mental retardation, cerebral palsy, sudden infant death syndrome, child abuse, and a host of other maladies related to prematurity.

In terms of overall morbidity, the greatest amount of long-term damage from teenage pregnancy comes from the frequent lack of a nurturing substrate required to adequately sustain the minds and souls of children. Children born into capable and loving families have enough obstacles to overcome on the way to productive adulthood. Why start life with two strikes?

Whatever one thinks about the rights or wrongs of premarital sexual activity, "it" is in fact occurring—a lot! To wish the situation away by moral pronouncements is like taking a stand for a flat earth.

CASUALTY FIGURES

The "casualty figures" bear recounting. In 1975, about 1.1 million pregnancies occurred in the United States to teenagers aged 15 to 19 years, which works out to one of ten teenage girls. More than half these pregnancies (55%) resulted in live births, 31% terminated in abortions, 14% resulted in fetal loss. In 1966, 3 million adolescents were believed to be sexually active; by 1975, the figure increased to 4.5 million—a 50% increase during a decade. In 1975, it was estimated that 55% of all unmarried 19-year-olds had engaged in intercourse.[1] There is every reason to believe that these upward trends in teenage sexual activity are continuing.

What about contraceptive practices? Kantner and Zelnik,[2] in their 1973 study of a national sample of never-married girls aged 15 to 19 years, found that about 20% in all age groups had always tried to protect themselves against pregnancy and that 53% of all the girls studied failed to use any contraception the last time they had had intercourse. Seventy-one percent of the youngest girls used no contraceptive.

The most commonly used contraceptives among all age groups are the pill and the intrauterine device (IUD). They are certainly effective in preventing conception, and they produce relatively few complications in the mature woman with a consistent sexual partner. There are important drawbacks, however, in advocating the use of these agents in young teenagers. One is the necessity to visit a medical facility for a prescription or insertion, which may deter a sizeable number of youths. Ryde-Bloomquist[3] says:

> Older teenagers, well motivated to using contraceptives, seem to accept the pill well, but younger teenagers have difficulties in following the pill prescription and may forget to take them as their habits often tend to be disorganized. The same side effects, eg, weight gain, nausea and headaches, have been noticed among teenagers as among adult women. Many teenagers are frightened by these symptoms and discontinue using the pill, often abruptly.

The IUDs also present problems for many nulliparas. The expulsion and/or removal rate for pain, bleeding, and infection is consistently greater among teenagers than among those 20 years of age or older.[4]

The diaphragm with a spermicidal preparation is a safe and effective contraceptive method that is enjoying a comeback as the complications of the pill and IUD become more publicized. Unfortunately, this approach requires a degree of sophistication and planning that adolescents usually lack.

SEXUALLY TRANSMITTED DISEASES

An ominous development that is not sufficiently appreciated in the pediatric community is the widening spectrum and severity of STDs. Our current sexual "freedom" is a direct result of both improved methods of contraception and antibiotics to treat syphilis and gonorrhea. The potential consequences of indiscriminate sexual behavior were made clear to youngsters growing up prior to World War II. Undoubtedly, faced with the graphic specter of lifelong pain, disability, and sterility, many chose celibacy.

The availability of penicillin put an end to the stern admonitions of scoutmasters, top sergeants, fathers, and physicians. However, the power of the "magic bullet" is starting to weaken.

The Communicable Disease Center, Atlanta, reported that in 1977, there were 9,556 children between the ages of 10 and 14 years, and 252,473 teenagers from 15 to 19 years old who were *reported* to be infected with gonorrhea.[5] In the last decade, effective treatment of gonorrhea required much more penicillin than previously: 4.8 million units of penicillin G procaine intramuscularly along with a 1-g dose of oral probenecid. In addition, there is the emergence of penicillinase-producing *Neisseria gonorrhoeae*. Few teenagers are aware that about 15% of infected female subjects get some kind of inflammatory disease such as salpingitis, endometritis, or peritonitis, leading to infertility.

Although such organisms as *Trichomonas vaginalis*, *Haemophilus vaginalis*, and pediculosis pubis are not frequent adolescent clinic problems, two STD "newcomers," *Chlamydia trachomatis*, and herpes simplex virus (HSV) have emerged as formidable public health problems. Nongonococcal urethritis is now two to three times more common in the United States than *N gonorrhoeae* infection. *Chlamydia trachomatis* has been identified as the etiologic agent in 40% to 50% of these cases.[6] In addition, recent studies documented *C trachomatis* as an important pathogen in mucopurulent cervicitis and salpingitis and as a common cause of conjunctivitis and pneumonitis in infants. Unfortunately, diagnostic services to detect this important and treatable pathogen remain few and far between.

Similar problems exist with genital HSV infections. This disease with its weeping, painful, itchy, and crusty lesions and frequent recurrences is just plain messy, a fact that might have more impact on a today-oriented adolescent than the more dangerous, yet remote, prospect of neonatal herpes infection. The incidence of genital HSV infection is uncertain, but in the STD clinic at the Harborview Medical Center in Seattle, one case of genital HSV infection is diagnosed for every 2.2 cases of *N gonorrhoeae* infection.[7] This would extrapolate to about 300,000 clinical infections per year in the United States.

Neonatal herpes infection may occur in as many as one in 3,500 deliveries. More than half the cases of neonatal herpes infection occur in babies born to young primigravidas. And at least half of the infants with neonatal herpes infection either die or have permanent neurologic sequelae.[8] Can there be any better justification for pediatric involvement in attempts to control STDs?

In recommending a contraceptive, it should be borne in mind that oral contraceptives actually enhance the probability of a woman acquiring gonorrhea from an infected male partner.[9] The users of IUDs also have a five to seven times increased risk of getting both gonococcal and nongonococcal salpingitis.[10] Thus, caution must be exercised in recommending either the pill or an IUD for women at high risk for STDs, ie, those with a variety of sexual partners.

RESURRECTING THE CONDOM

At this point, the reader might be excused for experiencing a sense of futility. Like rising inflation and shortages of energy, the problems outlined earlier seem so immense that nothing short of "restructuring society" (the intellectual equivalent of saying "it ain't no use") would seem to have any effect. A fallacy, though, in considering global problems is to seek all-encompassing solutions. There are no readily available *answers* to the twin problems of pregnancy and STDs in teenagers, but some different *approaches* must be tried. One such that makes immanent sense has been suggested by Felman[11]: promote use of the condom among sexually active teenagers. Can he be serious in recommending resurrection of the old prophylactic that has been the subject of so much locker-room humor through the years? He is indeed! Felman, who is with the Bureau of Venereal Disease Control of the New York City Health Department points out, with impeccable logic:

> The condom is the only device widely

available today that simultaneously provides both effective contraception and protection against STDs. In addition, it can be purchased over the counter at any pharmacy without a prescription. Condoms also completely eliminate major disadvantages of the IUD and the pill—their unwanted and sometimes dangerous adverse effects, the entire burden of which is borne by women.

Some further advantages:

(1) It can be conveniently kept in a pocket or purse for quick use when needed. (2) It is inexpensive, easily within the limits of most teens' financial capabilities. (3) It provides confidence and security to teenagers insecure about possible unwanted results of coitus because it is both a contraceptive and prophylactic. This is most important to teenagers, who often have many different sex partners. (4) The condom places the responsibility for both contracepti[on] and prophylactics on the initiator, generally, of sexual activity, the male. (5) The sexually active woman can carry condoms in her purse to protect herself in a doubtful situation against STDs even if she is already using the IUD or an oral contraceptive.

Felman rightly says: "A major effort by public health authorities and leading physicians to make the advantages of the condom as widely known as its few disadvantages would reap great dividends for STD control as well as reduce the incidence of teenage pregnancies." How can this be accomplished? By education and advertising. The allegation that teenagers will never use condoms can be countered by citing the study of Arnold and Cogswell.[12] They showed that when free condoms were made available to 3,000 teenagers through commercial outlets, usage increased from 20% to 91%.

The prevalent myth about the ineffectiveness of condoms, stemming from faulty products prior to World War II should be countered with data showing that, when properly and consistently used, condoms are now at least 97% effective in preventing pregnancy.[13] As mentioned previously, the story of STDs and the fact that not all of them can be cured (eg, herpes) along with their long-term effects on fertility and perinatal mortality and morbidity must be widely broadcast.

A QUANTUM LEAP

If physicians promoted condom usage in the course of their professional activities (ie, in medical offices, clinics, public health departments, etc) it would constitute a *step* forward in reducing pregnancies and STDs. A quantum *leap* in the campaign, however, would occur if physicians used their influence to encourage mass advertising of condoms. Think of it: no grants, no federal "initiatives," just allow the master of motivation, the American advertising industry, to display its talents.

Felman[11] says:

> The key to the success of such an effort is in persuading the National Association of Broadcasters to allow condom advertising on radio and television and in convincing the copy-review board of newspapers and magazines in general circulation to do the same. The paradox of health values in America today is clearly illustrated by the fact that cigarettes, which are known to cause disease, are prominently advertised in the press, while condoms, which prevent disease, are not considered suitable for advertisements. This practice is responsible for the general public's, especially the teenager public's, continued ignorance concerning the many advantages of the condom.
>
> Organized medicine and public health can take the lead here in changing this by bringing their collective weight to bear on the media to reverse this policy.

It is possible that the appearance of one or two condom advertisements on Monday night football programs would do more to lower teenage pregnancy rates than five years' worth of federally funded adolescent health programs.

Naturally, there will be opposition both from those who believe that contraception is immoral and from those who would like to believe that no sexual activity takes place outside marriage. By advocating condom usage to those who are already sexually active, the physician does not condone promiscuity. Responsible social behavior should be a component of all health education. Those who crusade against all abortions should be challenged to make what, for them, is admittedly a hard choice. Is not prevention of pregnancy preferable to abortion?

Physicians who bear witness to the consequences of unwanted pregnancies and herpes encephalitis must apply the moral yardstick. In this case, inaction amounts to acquiescence. We cannot solve the whole problem, but we have to take some tangible steps in the right direction. In an address to the French bishops, Albert Camus[14] said, "You dream of a world in which no children starve; I dream of a world in which fewer children starve."

Use of Side-Hole Endotracheal Tube Adapter for Tracheal Aspiration

A Controlled Study

Ehud Zmora, MD, T. Allen Merritt, MD

• **An alternate tracheal aspiration procedure using a side-hole endotracheal adapter was used in conjunction with transcutaneous oxygen (T_cPO_2) monitoring in 13 mechanically ventilated newborn infants. Decline in T_cPO_2 during suctioning and drop in neonatal heart rate were both substantially reduced using a procedure designed to preserve mean airway pressure. When compared with the routine procedure of disconnecting the endotracheal tube from the ventilator and suctioning via an end-hold adapter, this approach prevented precipitous and dangerous hypoxemia.**

(*Am J Dis Child* 134:250-254, 1980)

Endotracheal tube suctioning is an obligatory procedure in patients requiring prolonged mechanical ventilation. This therapeutic procedure is often associated with adverse physiological reactions, including hypoxia,[1,2] apnea, and bradycardia.[3] To our knowledge, no clearly preferential technique has emerged to prevent or ameliorate such adverse reactions.[4] New monitoring techniques, especially transcutaneous oxygen (T_cPo_2) monitoring, are available for more accurate evaluation of different techniques and devices used for endotracheal suctioning.

We report the experience of the infant Intensive Care Nursery at the University of Rochester, NY, using the endotracheal tube adapter with side holes compared with the standard end-hole adapter for endotracheal suctioning in infants requiring endotracheal intubation for mechanical ventilation as assessed by continuous T_cPo_2, neonatal heart rate, and airway pressure monitoring.

MATERIALS AND METHODS

Infants requiring mechanical ventilation (positive peak inspiratory pressure and positive end expiratory pressure [PEEP]) for respiratory distress syndrome, pneumonia, perinatal asphyxia, and gastrointestinal surgery were studied. The infants were intubated with endotracheal tubes with internal diameters of 3.0 and 3.5 mm and they were ventilated using a Baby Bird ventilator. The vacuum source was routine apparatus-Suction Regu-Gage set to generate negative pressure of 40 to 50 mm Hg. Suction catheters, No. 6F and 8F, were used. The suction procedures were performed by the nursing staff as follows: disconnect from ventilator, instillation of

0.2 to 0.5 mL (0.9%) saline down the endotracheal tube, 5 s; bagging, 20 s; suction-head turn to the right, ≤ ten s; bagging, 20 s; suction-head turn to the right, ≤ ten s; bagging, 20 s; suction-head turn to the left, ≤ ten s; bagging, 20 s; suction-head turn to the left, ≤ ten s; bagging, 20 s; and reconnection to ventilator and oropharyngeal suction, ten s.

An identical suction procedure at the next scheduled pulmonary toilet, usually one to two hours later, was performed after replacing the endotracheal tube adapter with an endotracheal tube adapter with side holes (Fig 1). Instillation of saline and suctioning were done through the right or left side holes of the adapter, without disconnecting the endotracheal tube from the respirator. Pulmonary inflation during tracheal suctioning using the side-hole adapter was maintained by the Baby Bird ventilator at the same peak inspiratory pressure rate, PEEP, and fraction of inspired oxygen (FIO_2) pressure as preceding the procedure. Infants undergoing tracheal toilet using the end-hole adapter were disconnected from the ventilator during the suctioning procedure and manual inflation of the ventilator bag was performed after reconnecting the infant to the ventilator when presuctioning ventilatory rates were less than 30 breaths/min. When presuctioning ventilation rates were greater than 30 breaths/min, mechanical ventilation was reinstituted at the same rate on reattachment to the ventilator after suctioning. Continuous T_cPo_2 monitoring during all suctioning procedures was done with the Oxymonitor SM 361.

Proximal airway pressures at the level of the endotracheal tube adapter (proximal airway pressure) were measured continuously from a side port T-shaped connecter adapted to the endotracheal tube with a physiological pressure transducer and displayed on a strip chart recorder.

Assuming that the ventilation waveform approximates a square wave configuration (Fig 2, A), mean airway pressure (MAP) was calculated prior to and during the suctioning procedure according to the equation in Fig 2, B.

For every paired study on each baby, tracheal aspirations were performed by the same nurse who alternately used the regular end-hole adapter and the side-hole

adapter. The same monitor was used for determining neonatal heart rate and recording this simultaneously with the airway pressure wave forms. This study was reviewed and approved by the Committee for the Protection of Human Subjects at the University of Rochester.

RESULTS

Thirteen babies with gestational ages from 27 to 40 weeks and birthweights ranging from 900 to 4,400 g who required tracheal aspiration as a part of routine clinical care were included in 19 paired studies. Table 1 lists the number of procedures and the decrease in T_cPo_2 during suctioning using both the end-hold and side-hole adapter. Percent decline in T_cPo_2 during each procedure was calculated and the mean of all procedures was tabulated in Fig 3. In all but two studies, percent decrease in T_cPo_2 was less using the side-hole adapter. The magnitude of these differences was significantly less ($P < .01$) in 12 of 19 studies on all occasions. In an attempt to explain these differences, MAPs resulting from the suctioning procedures were calculated. Mean airway pressures remained higher when using the side-hole vs the end-hole endotracheal tube adapter. As given in Table 1, proximal airway pressures dropped to 0 cm H_2O using the end-hold adapter during suctioning when the tube was disconnected from the ventilator. When using the side-hole adapter, a fraction of the MAP was maintained. A comparison between the percent decrease in T_cPo_2 and the decline in MAP for both suctioning routes is given in Table 3. These data clearly indicate that in 17 or 18 paired studies, the greater the decrease in MAP, the more severe was the decline in T_cPo_2.

The importance of these findings as seen in Fig 4 indicates that in our 18 infants the percent decrease in T_cPo_2 as related to the simultaneous drop in MAP was substantially greater in infants in whom end-hole endotracheal tube suctioning was used. Occurrence of bradycardia was significantly less ($P < .01$) in six infants, not different in 11, and considerably worse in one infant when the side-hole adapter was compared with the end-hole suctioning (Fig 5).

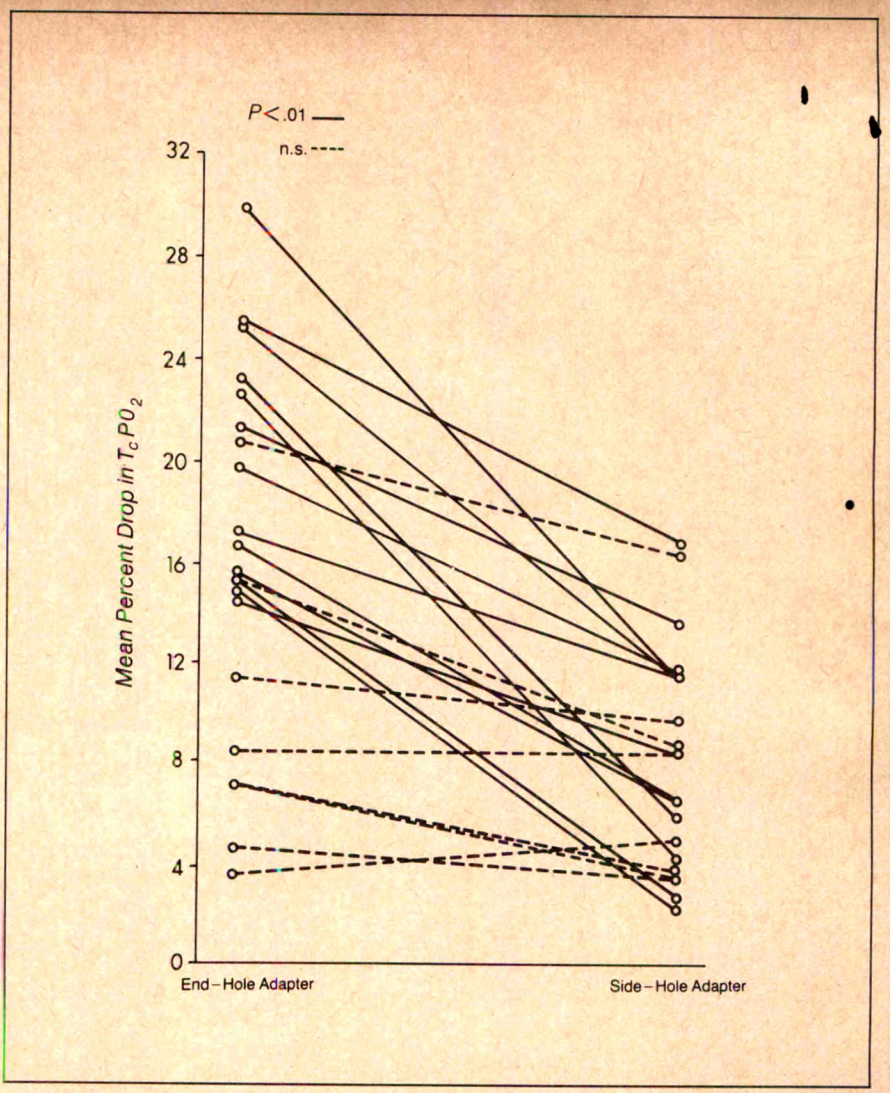

Fig 3.—Comparison of percent drop in transcutaneous oxygen (T_cPo_2) in 19 paired tracheal aspiration studies (194 procedures). Solid lines indicate substantial reduction in percent decrease of T_cPo_2 using side-hole adapter. Broken lines indicate decrease that was not statistically significant.

*T_cPo_2 indicates transcutaneous oxygen; MAP, mean airway pressure.

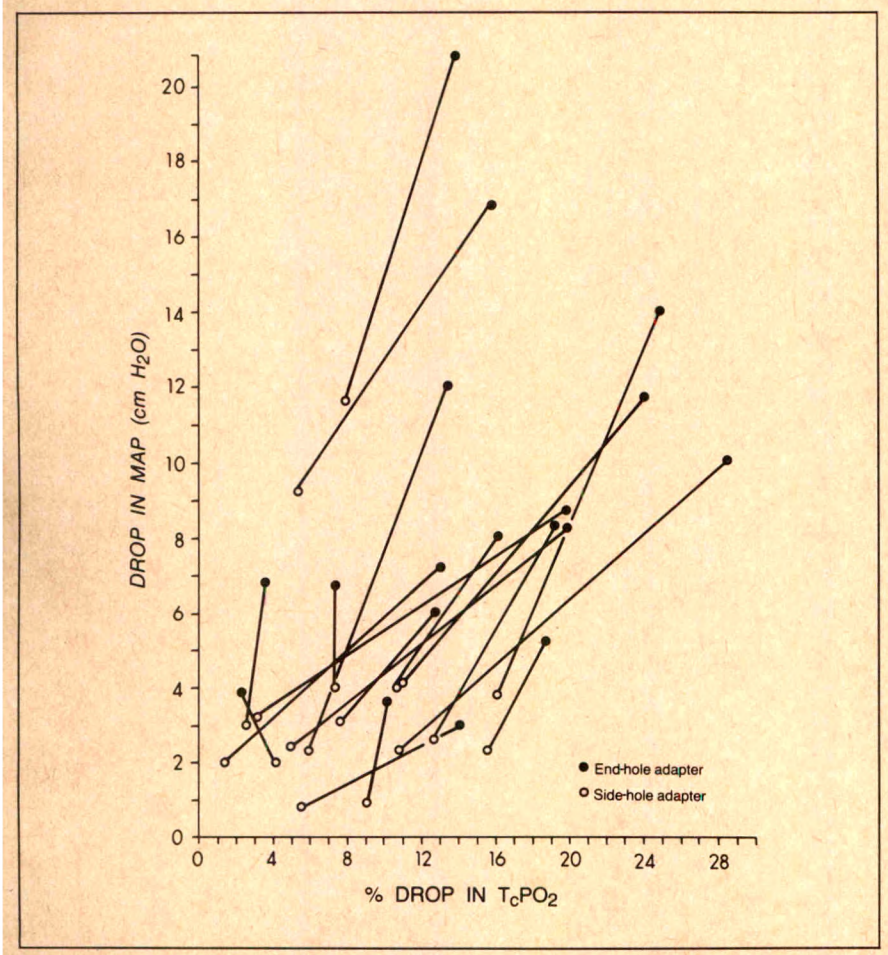

Fig 4.—Decline in transcutaneous oxygen (T_cPo_2) associated with endotracheal tube aspiration compared to decrease in mean airway pressure in 18 paired studies (178 procedures). Greater decrease in mean airway pressure, more pronounced decline in T_cPo_2.

COMMENT

A host of disturbing complications has been reported in association with neonatal endotracheal tube suctioning. Pneumothorax,[5] bronchial perforation,[6] atelectasis,[7] apnea,[8] hypoxemia,[2] and bradycardia[3] have been reported in preterm and term infants undergoing endotracheal tube aspiration.

Fox et al[9] documented substantial decreases in Pao_2 after suctioning accompanied by diminished inspiratory and expiratory resistance that only returned to normal after a period of hyperventilation. The same authors found reduced lung volume suggestive of atelectasis that may prolong the period of recovery from tracheal airway aspiration. Chest percussion and postural drainage have been reported to elevate Pao_2[10] in infants after suctioning, yet the amount of secretions removed by physiotherapy or tracheal aspiration has not been correlated to improvements in T_cPo_2 or promptness in resolution of pulmonary disease.[11] Recently, the benefits of frequent airway suctioning have been questioned, and current nursery techniques may require modification.

Long et al[12] demonstrated substantial drops in T_cPo_2 levels in preterm and term infants undergoing pulmonary toilet. Using a side-hole endotracheal tube adapter, Cabal and associates[13] found a smaller drop in oxygen saturation and less bradycardia. Stimulation of pulmonary irritant reflexes by the suction catheter may account for apnea[11] and frequently is associated with bradycardia. Anticipation of hypoxemia often encourages the use of either preoxygenation or hyperventilation, yet the advantages of the latter approach have not been thoroughly studied.

Our findings of diminished decrease in T_cPo_2 in the controlled use of side-hole endotracheal tube aspiration as compared with ventilator disconnection and end-hole aspiration result from maintenance of MAP throughout the procedure. Mean airway pressure has been shown to inversely correlate to the magnitude of the alveolar-arterial oxygen gradient[14] and to a useful clinical measure of pressures transmitted to the airway.[15] By

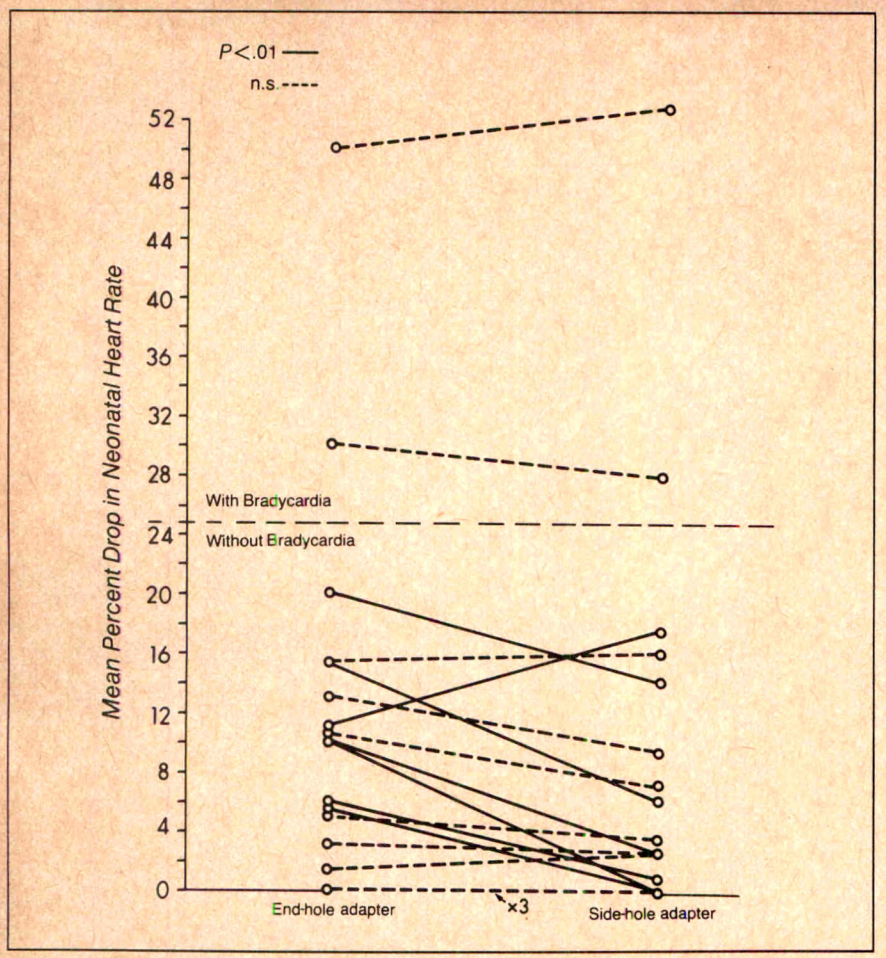

Fig 5.—Comparison of decrease in neonatal heart rate using both suctioning techniques in 18 paired tracheal aspiration studies (178 procedures). Less drop in neonatal heart rate was observed when side-hole adapter was used for suctioning.

retaining a portion of presuctioning airway pressure during tracheal aspiration using our technique, T_cPo_2 remained within acceptable ranges making preoxygenation unnecessary.

Although the drop in neonatal heart rate was diminished in some infants undergoing tracheal aspiration using the side-hole technique, no improvement in the heart rate was observed in most infants. This may suggest that pulmonary irritant receptors, rather than hypoxemia, play a major role in heart rate decrement during suctioning.[16]

The side-hole endotracheal tube adapter is not without disadvantages. The time required for introducing the suction catheter into the endotracheal tube is slightly longer. Furthermore, the need to turn the infant's head from side to side requires the service of two persons to maintain a stable airway-ventilator hose combination. In spite of these disadvantages, our experience suggests that hypoxemia can be minimized by our technique. There is a need to compare proximal and distal airway pressures using this technique to determine whether change in T_cPo_2 reflect alterations of pressures within the lung. Furthermore, continued studies are warranted during the acute and convalescent stages of a variety of pulmonary diseases in infants and children.

Assistance was provided by the nursing staff of the Intensive Care Nursery and by Larry Ten Eyke AART, of the Respiratory Therapy Department, University of Rochester, Rochester, NY. Corometrics 512 Neonatal Monitors were provided by Craig Castle. The endotracheal tube adapter with side holes (Neonatal C/D Adapters) was provided by Novametrix, Medical Systems Inc, Wallingford, Conn.

Sexual Abuse of Boys

Norman S. Ellerstein, MD, J. William Canavan, MD

• **In a retrospective review of 145 sexually abused children, 11% were male. The boys were more likely to be assaulted in a public place than were girls, and boys were more prone to physical injury. The relationship of the perpetrator to the child was similar for boys and girls as was the age of the children. This study emphasizes the existence of boys as victims of sexual abuse.**

(*Am J Dis Child* 134:255-257, 1980)

Recognition of physical abuse of children has dramatically improved since its description in the medical literature in the early 1960s.[1] However, recognition and treatment of sexually abused children has been less aggressive.[2] In the literature, the media, and the clinical setting, sexual abuse is usually stereotyped as a male perpetrator and a female victim. This study seeks to assess the importance of male children as victims of sexual abuse and to determine whether or not they pose problems different from those of girls as victims.

METHODS

A chart review was conducted for each patient coming to the Children's Hospital of Buffalo emergency room in the period from Jan 1, 1976, to Dec 31, 1978, with a chief complaint related to sexual abuse. The population served by the emergency room is preponderantly urban. The patient histories, physical examination, and specimen collection for laboratory procedures were performed by resident physicians in obstetrics and gynecology for the female patients and by pediatric residents for the male patients. Each was carried out according to a protocol, with special forms for recording the history, the results of the physical examination, the documentation of evidence collection, the methods of treatment, and the results of follow-up.

The review addressed the following aspects: the age and sex of the patient, the relationship of the patient to the alleged perpetrator, the location at start of the episode, physical findings suggesting injury of a sexual nature, physical findings suggesting injury of a nonsexual nature, and laboratory findings including presence and location of spermatozoa as well as results of tests on serologic and culture specimens taken. Male and female patients were compared with respect to the victim's age, relationship of the perpetrator and the victim, and the presence of positive physical findings or laboratory results. For this review, sexual abuse is defined as "the exposure of a child to sexual stimulation inappropriate for the child's age, level of psychosocial development, and role in the family."[3]

RESULTS

One hundred seventy patients younger than 21 years old presented as victims of sexual abuse. There were 154 female patients (91%) and 16 male patients (9%). There were 50 cases in 1976 (8% boys), 52 cases in 1977 (6% boys), and 68 cases in 1978 (13% boys). Of the 170 patients in the study, 145 gave histories consistent with the chief complaint. Of the other 25 cases, all of whom were girls, eight were situations of adolescent sexual activity by mutual consent, but arousing parental concern. The other 17 cases had insufficient data or did not meet the criteria to be considered a case of sexual abuse. All 16 boys' histories were consistent with the definition of sexual abuse used in this study. Therefore, of the 145 patients with histories of sexual abuse, 16 (11%) were male and 129 (89%) were female.

Male patients ranged from 3.3 to 16.4 years of age, with a mean age of 9.7 years. Female patients ranged in age from 0.3 to 20.2 years of age, with a mean age of 10.2 years. The relationships between the patients and the perpetrators are presented in Table 1. All the perpetrators were male for both male and female patients.

Table 2 describes the male patients. Of the 16 male patients, 14 had adequate information to determine where the incident began. Five cases (36%) occurred at home, and nine (64%) began in a public place (eg, street or park). Of the 129 female patients' records, 120 were adequate to indicate where the incident began. Of these, 44 cases (36.6%) occurred at home, 38 (31.6%) began in other familiar places (eg, the home of a friend or relative) and 38 (31.6%) began in a place of public access.

Eight of the 16 boys (50%) had positive findings on physical examination. Seven boys had evidence of anal

or perianal trauma. Patient number 5 had evidence of recent abrasions, but not in the genital or anal area. Two of the seven boys with anal trauma also demonstrated multiple ecchymoses on other parts of their bodies. Only one boy had spermatozoa present in the rectum; there was no semen recovered from the oral cavity of any of the boys. None of the boys had cultures positive for gonorrhea or a positive VDRL when seen at follow-up. Forty-seven of the girls (36%) had positive findings on physical or laboratory examination. Fourteen of these girls demonstrated injuries only in nongenital areas.

COMMENT

Historically, widely varying cultural attitudes have determined concepts of sexual abuse. In Western society, there is currently some professional consensus regarding the term. The definition applied in this study for review of cases[3] is not unlike that of Kempe[2]: "the involvement of dependent, developmentally immature children and adolescents in sexual activities that they do not fully comprehend, to which they are unable to give informed consent, or that violate the social taboos of family roles." Within that context, however, available studies give little attention to the male child as an entity distinct from girls who are victims of sexual abuse.[4-7] By emphasizing diagnosis and management of cases of female patients with no mention of male patients beyond their incidence, the victim of sexual abuse is implicitly stereotyped as female while the assailant is portrayed as male.

Table 1.—Relationships of Perpetrators to Victims

Perpetrators	No. (%) Boys (n = 16)	No. (%) Girls (n = 129)
Stranger	9 (56)	57 (44)
Family member	2 (13)	32 (25)
Babysitter	1 (6)	8 (6)
Others known to patient	4 (25)	32 (25)

The current study is biased by the fact that patient selection was based on initial complaint and not final diagnosis. As such, only children with overt complaints of sexual maltreatment were able to be identified. This procedure may have selected a patient population with a higher frequency of positive findings. Children who come to medical attention because of vaginal or urethral discharge, abdominal pain, or behavioral symptoms and who are subsequently found to have been sexually abused are an important group, but they could not be identified in this study. Because obstetric-gynecology residents examined the female patients and pediatric residents examined the male patients, artificial differences in historical and physical findings between boys and girls may have been created.

In this study, boys accounted for 11% of those children giving a history of sexual abuse. This percentage is similar to that reported by deFrancis[8] in 1969 in which 16% of children appearing as victims of sexual abuse were male. Jaffe et al[4] reviewed sexual offense complaint records of the Minneapolis Police Department for 1970 and found that 12% of the victims younger than 16 years old were male. Copeland et al[9] reported that 14% of the victims in their study were male. In the latter two reports, as in our own, the patients presented explicitly as victims of sexual abuse. The incidence of fortuitously discovered covert victims of sexual abuse is not well known, although it is interesting that a similar percentage in a study of children with gonorrhea were male (15 of 100 children 14 months to 14 years old).[10] Why a higher proportion of sexual abuse victims are not male is not known. Brant and Tisza[3] ask whether there are indeed fewer male victims or if "other factors contribute to males seeking attention less often."

As noted in this study, the sexual abuse itself results in physical trauma

Table 2.—Features of Male Patients

of a large percentage of the boys. Others have reported sexual abuse precipitating gonorrhea,[10] herpes genitalis,[11-13] syphilis,[14] group B streptococcal infection, chancroid, lymphogranuloma venereum, lymphogranuloma inguinale, pubic lice, scabies,[15] presence of foreign bodies,[4] the traumatic lesions of coexisting (nongenital) child abuse,[4,16] and death by asphyxiation.[17] Psychoemotional sequellae are less clear-cut. Kempe[2] believed that boys suffer greater psychological trauma than girls. Glueck[18] noted that almost one half of all pedophiliacs experienced sexual abuse as boys. Behavioral changes after recurrent sexual abuse by parents have been reported.[19] Yet others temper their impression of the psychoemotional impact and speak of children in general, saying behavioral changes are variable, complex, multifactorial, often not immediately evident, and still the subject of much study.[20]

There are no differences between boys and girls with respect to the age at which the child comes to the attention of the health professional or with respect to the sex of the perpetrator. Since it was not consistently determined for how long the sexual abuse was allowed to continue before seeking help, it is unknown whether sexual abuse of boys remains covert, and therefore unresolvable, for longer periods than for girls. The current study is consistent with those of deFrancis[8] and Jaffe et al[4] as to the age of the victims.

Seven of the 16 boys (44%) knew their assailant. This is not statistically significantly different from the girls (56%). Most studies agreed that a majority of the patients know their assailants.[8,21,22] Two thirds of the boys' abusive incidents began in a place of public access. Only one third of the girls' incidents began in a public place. That the incident began in a public place did not necessarily mean that the assault was completed there, but this describes the location in which the child was vulnerable. Because of the small size of our male cohort, we are unable to determine if the higher percentage of boys abused in public places is truly characteristic of boys as victims.

Eight of our 16 male patients (50%) demonstrated genital or nongenital injuries. This is a high incidence in comparison with girls or children in general in other studies. In a project reviewing adult women and girls in Washington, DC, by Hayman and Lanza,[23] 7.1% of the children had major injuries (combined genital and nongenital), but the authors did not quantitate or characterize the minor injuries. In Voigt's study,[22] serious injury of girls younger than 15 years old was unusual, occurring in only 0.7%. Injuries to boys are not mentioned.

The high percentage of injuries in our study is mostly contributed by anal or perianal lesions. The anus is the only readily available orifice in the male perineum. It is also of smaller caliber than the mouth or female vagina. Paul[16] described the shearing force required to insert a penis into the previously unviolated anus of a young child as sufficient "to rupture the delicate and poorly supported blood vessels at the anal verge," producing local hematoma and swelling. Depending on the force and repetition applied, tearing of anal structures may occur.

It is important to remember that 50% of the boys and 64% of the girls demonstrated no physical or laboratory evidence of sexual contact. If the physician relies on objective findings to confirm a diagnosis of sexual abuse, the majority of these children might not receive appropriate intervention and treatment.

IMPLICATIONS

This study suggests that boys are more commonly victims of sexual abuse than is generally appreciated. Boys are similar to girls in the type of perpetrator who assaults them and in the age group at which they appear for medical examination. Although they are equally prone to assault in their own homes, boys are more likely to be assaulted in public places and more likely to be physically injured by the incident. Parents, health care providers, and child advocates need to be alerted to the existence of the male child sexual abuse victim so that prevention and timely intervention can be provided. In evaluating traumatic injuries, genital infections, and psychoemotional disorders in boys of any age, the possibility of sexual abuse must be considered.

Treatment of Bartter's Syndrome With Indomethacin

Eduardo H. Garin, MD; Robert S. Fennell III, MD; Abdollah Iravani, MD; George A. Richard, MD

• Two patients with Bartter's syndrome were treated with indomethacin (2 mg/kg/day). The administration of the drug resulted in weight gain; a decrease in the rate of urinary excretion of sodium and inorganic phosphate suggesting an increase in proximal tubular reabsorption; an increase in serum potassium concentration, with a transient decrease in the rate of urinary potassium excretion in one patient; and a decrease in plasma renin activity and in the rate of urinary aldosterone excretion. Since indomethacin has been shown to inhibit prostaglandin synthetase, these observations support the hypothesis that prostaglandin excess is a basic pathogenic mechanism in Bartter's syndrome.

(*Am J Dis Child* 134:258-261, 1980)

Bartter's syndrome is defined as the association of hypokalemia, metabolic alkalosis, hyperaldosteronism, hyperreninemia, normal blood pressure, and hyperplasia of the juxtaglomerular apparatus.[1]

Although the clinical, biochemical, and histologic findings have been well defined, the pathogenesis of the disease has remained obscure. Reversal of the abnormal findings with prostaglandin synthetase inhibitors (indomethacin,[2-6] aspirin,[6,7] ibuprofen,[5,6] naproxen[8]) has suggested a pathogenic role for prostaglandins. We describe two patients with Bartter's syndrome who underwent a clinical trial of indomethacin to test the hypothesis that prostaglandin excess is a basic pathogenic mechanism in these patients.

SUBJECTS AND METHODS

Two patients who fulfilled the diagnostic criteria for Bartter's syndrome were admitted to the Clinical Research Center, W. Shands Teaching Hospital, Gainesville, Fla.

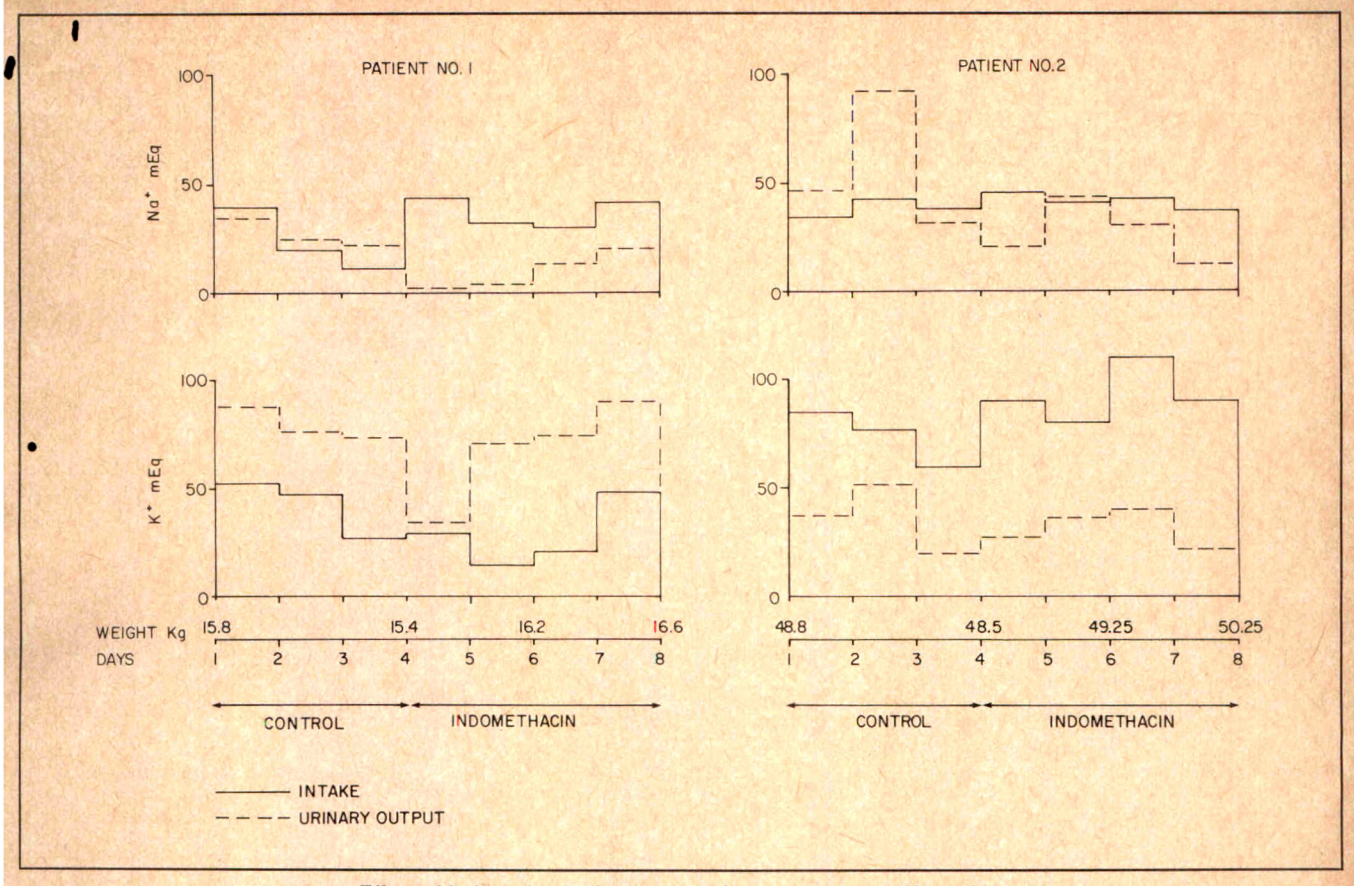
Patient 1 was a 7-year-old girl who was initially hospitalized because of seizures at age 2 weeks. At that time, polydypsia and polyuria were noted. Subsequent follow-up showed poor growth, persistence of the polyuria and polydypsia, constipation, and hypokalemia. For the first 5 years of life, she was treated only with potassium supplements. Because of persistence of symptoms, and a serum potassium level of 2.7 mEq/L, triamterene was given in a dosage of 4 mg/kg/day together with potassium supplements. One month later, because of bone demineralization, calcium supplements and cholecalciferol (vitamin D_3) (5,000 units/day) were started. Despite these efforts, she had rickets, bone pain, and persistent hypokalemia develop. A one-month course of propranolol hydrochloride (2 mg/kg/day) did not affect these clinical and biochemical abnormalities. At age six, she had tetany develop that was controlled with intravenous calcium gluconate infusion; cholecalciferol dosage was increased to 30,000 units a day. The rachitic lesions healed although she continued to have hypokalemia, polyuria, polydypsia and her height and weight remained below the third percentile.

Patient 2 was an 18-year-old man who was recognized to be small for age and to have had polydypsia at age 7 months. Hyposthenuria and hypokalemia were first noted when he was 5 years old, and he was treated with hydrochlorothiazide and potassium supplements. During the subsequent year, there was no improvement in his symptoms; his serum potassium level was 2.1 mEq/L. He was given a low-salt diet and potassium supplements. Three years later, because of persistent hypokalemia, triamterene (100 mg twice daily) and potassium salts were given with inconsistent results. His serum potassium level varied during the succeeding years from 3.1 to 3.8 mEq/L, and there was no improvement in his growth rate and polyuria. Nephrocalcinosis was noted at age 14 years. At age 17 years, he had a growth spurt associated with sexual maturation, which brought him up to the fifth percentile in height.

Informed consent was obtained prior to the study. All medications except potassium supplements were discontinued for one week prior to admission. Patients were offered a diet calculated to supply 50 mEq of sodium daily. Potassium in the food amounted to 32 mEq/day for patient 1 and 40 mEq/day for patient 2. The food was weighed, and data in the US Department of Agriculture's *Handbook No. 8* were used to calculate sodium and potassium.[9] Fluids were given ad libitum and caloric intake was held constant. Amounts of potassium supplements were recorded daily.

During a three-day control period and during a subsequent four-day period of indomethacin therapy, 24-hour urine collections were obtained. Indomethacin was administered in a dosage of 2 mg/kg/day given in three divided doses with meals.

Serum samples were obtained with the patients fasting and in the supine position on days 1, 4, and 6 and at the completion of the study on day 8. Serum and urine samples were analyzed for sodium, potassium, inorganic phosphate, calcium, and creatinine with an automated system of chemical analysis. Blood was obtained on days 1 and 8 for plasma renin and parathyroid hormone (PTH) tests, which were determined by radioimmunoassay. Venous blood pH and plasma base excess were determined on days 4 and 8. Urine collected on days 1 and 7 was analyzed for aldosterone. Fractional excretions (F_Es) of sodium, potassium, calcium, and inorganic phosphate were determined on days 1, 4, 6, and 8. Fractional excretion represents the fraction of a filtered solute that is excreted, and it is thus inversely related to tubular reabsorption. It is calculated by dividing the ratio of urinary-plasma (U/P) concentration of the solute by the U/P creatinine



Effect of indomethacin therapy on urinary excretion of Na and K.

ratio, and it is expressed as the percent of filtered solute excreted:

$$F_E \text{ of solute} = (U/P \text{ solute})/(U/P \text{ creatinine} \times 100)$$

Normal values for sodium are 0.5 to 1.0; for calcium, 0.5 to 1.0; for inorganic phosphate, 2 to 20; and for potassium, 10 to 20.

RESULTS

Clinical and laboratory findings are provided in the Table and Figure. During the control period, the data for both patients are consistent with the diagnosis of Bartter's syndrome. The serum potassium level was at the lower limits of normal in patient 1 (3.5 and 3.7 mEq/L), whereas patient 2 had persistent hypokalemia (serum potassium level of 3.1 and 3.2 mEq/L). The serum chloride level was low in patient 1. Both patients had elevated levels of urinary aldosterone excretion and of plasma renin activity. Serum PTH concentration was normal in patient 2.

In both patients, the rate of urinary excretion of sodium exceeded sodium intake during most of the control period while they were losing weight. At the end of the control period, the F_Es of sodium and inorganic phosphate were within normal limits: 0.53 and 2.41 in patient 1, and 1.01 and 18.4 in patient 2. The F_Es of calcium and potassium were higher than normal at the end of the control period in patient 1 (3.36 and 68.5); in patient 2, the F_E of calcium was 3.80, determined on the first day of the study, and the F_E of potassium was 26.90 on the last control day.

The day after indomethacin therapy was started, both patients gained weight (0.6 kg in patient 1 and 0.7 kg in patient 2). The increase in weight was maintained during the next four days without blood pressure changes. Patient 1 had a decrease in urinary output from 1,120 mL/24 hr to 515 mL/24 hr during the first day of indomethacin therapy. However, the urinary output returned to control values by the end of the trial. The serum sodium level remained unchanged after administration of indomethacin, whereas the serum potassium level increased and the blood pH decreased slightly, as did plasma base excess.

In both patients, sodium intake exceeded the rate of urinary sodium excretion during the indomethacin trial, and there were decreases in the F_Es of sodium, inorganic phosphate, calcium, and potassium. The maximal decrease of the F_E was found the day of the highest serum potassium concentration (second day of indomethacin therapy for patient 1 and fourth day of therapy for patient 2). In patient 1, the F_Es of sodium, calcium, and potassium had returned to or exceeded the control levels by the end of the therapeutic trial, with a concomitant decrease in the serum potassium concentration although still higher than control levels. Furthermore, despite the initial decrease in the F_E of potassium, her urinary potassium value exceeded the oral intake throughout the trial. At the end

Laboratory Data								
	Day of Study							
	Patient 1				Patient 2

of the trial, there was a substantial reduction in plasma renin activity and urinary aldosterone excretion. At the same time, serum PTH levels remained within normal limits.

COMMENT

Patients with Bartter's syndrome have findings that are compatible with overstimulation of the renin angiotensin and the prostaglandin synthetase systems. Elevated levels of serum[7] and urinary prostaglandin E_2[4,6,7] have been reported in this condition. Proliferation of the medullary interstitial cells thought to produce prostaglandins[10,11] has been described.[3-5] The increase in plasma renin concentration, the rate of aldosterone excretion, and the hyperplasia of the juxtaglomerular apparatus are essential characteristics of Bartter's syndrome.[1] Furthermore, in these patients, a close correlation has been found between the concentration of urinary prostaglandin, the level of renin secretion and the rate of urinary aldosterone excretion.[4,6,7]

Patients with Bartter's syndrome have a decreased extracellular volume[2] and total exchangeable body sodium.[2] Since prostaglandin E_2 has been demonstrated to be natriuretic,[12] it has been postulated that the increase in prostaglandin would cause a primary renal salt wasting defect leading to sodium depletion with secondary activation of the renin angiotensin system resulting in hyperaldosteronism.[2]

Studies of renal tubular function in patients with Bartter's syndrome have shown decreased proximal[13,14] or loop of Henle[14-17] reabsorption of filtrate. The tubular reabsorptive defect can be partially or totally compensated for by an increase of the distal tubular reabsorption. Thus, most patients with this syndrome do not have obligatory salt loss because the increase in aldosterone secretion compensates for the tubular reabsorptive defect by augmenting the distal reabsorption of sodium.[18,19] However, this increases the urinary potassium loss by stimulating the sodium-potassium exchange at the distal tubule.

In our patients, the administration of indomethacin resulted in weight gain without blood pressure change, in sodium retention, and in an increase in the serum potassium concentration and improvement in the metabolic alkalosis. At the end of the trial, there was a decrease in the plasma renin concentration and the rate of urinary aldosterone excretion. These responses to indomethacin are consistent with the theory of increased prostaglandin production as a factor in the pathogenesis of Bartter's syndrome.

During indomethacin therapy, both our patients had an increase in tubular reabsorption of sodium and inorganic phosphate. Inorganic phosphate can be reabsorbed either at the proximal or distal segment of the nephron.[20] The proximal reabsorption is linked to sodium reabsorption and follows two mechanisms (PTH dependent and PTH independent).[20] The distal reabsorption is important only in the absence of PTH.[21] During indomethacin therapy, patient 1 had a normal PTH level, while the PTH level increased in patient 2. This suggests an increase in proximal tubular reabsorption of sodium and inorganic phosphate after prostaglandin inhibition, linked to the PTH-independent reabsorptive mechanism.

The decrease in the F_E of sodium seen in patient 1, before indomethacin therapy was begun, represents an adaptation to the reduced sodium intake. However, the further decrease in the F_E of sodium observed on the second day of indomethacin therapy cannot be attributed to this adaptive mechanism since it was well beyond expected levels. A 50% reduction of sodium intake, as in this case, would lead to a 50% reduction of the F_E. The F_E of sodium decreased from 0.78 to 0.14, representing an 80% reduction.

The increase in sodium reabsorption was maximal on the first day of therapy for patient 1 and on the fourth day for patient 2. However, although the sodium intake for patient 1 continued to exceed the urinary output throughout the trial, her F_E of sodium was approaching control levels on the fourth day of therapy. Probably, the

patient was in the process of achieving a new state of equilibrium based on an expanded extracellular volume. The volume expansion would decrease the proximal as well as distal sodium tubular reabsorption.[22] However, the increase in distal delivery of sodium in the presence of a still-activated renin aldosterone system may account for the increased rate of potassium excretion noted in patient 1 after the first day of indomethacin therapy by augmenting the sodium-potassium exchange at the distal tubule.

The serum potassium level increased in patient 1 despite the fact that the rate of urinary excretion of potassium exceeded the oral intake during indomethacin therapy. This increase in the serum potassium level was associated with sodium retention that would increase the sodium content of the RBC because of the known defect of the RBC membrane sodium-potassium adenosine triphosphatase in Bartter's syndrome.[23,24] The resultant displacement of intracellular potassium could then account for the increase in extracellular concentration of the cation.

Patient 1 had higher pretherapy and posttherapy renin levels than patient 2, and the metabolic indices for patient 1 improved less after indomethacin therapy. The higher renin levels may have reflected greater prostaglandin concentration[4,6,7] and, hence, less impact of indomethacin therapy on prostaglandin production.

The primary event leading to the increase in prostaglandin production in Bartter's syndrome is unknown although hypokalemia has been considered as the etiologic factor.[25] Prostaglandin E_2 levels are elevated in dogs depleted of potassium by hemodialysis.[26] However, the animals also had an increase in intravascular volume and serum sodium concentration. These findings are opposite to what occurs in patients with Bartter's syndrome.[1,2] In the canine experiment, renal prostaglandin production could have been secondary to the expanded vascular volume or the increase in serum sodium concentration.[27]

Increased prostaglandin synthesis as a basic pathogenic mechanism in Bartter's syndrome is an attractive hypothesis. Our patients seemed to benefit from the prostaglandin synthetase inhibitor therapy. Of all available drugs, indomethacin seems to be the most effective.[7] A wide range of opinion exists as to the severity and practical importance of untoward reactions to indomethacin. Nausea, vomiting, abdominal pain, headaches, and dizziness are dose dependent, and the reported frequency has varied greatly. However, because fatalities and morbidity secondary to peptic ulceration and hepatic toxic effects have been reported,[28] this mode of therapy should be reserved for patients whose metabolic abnormalities cannot be controlled by potassium supplements and antialdosterone agents alone.

This work was supported by Clinical Research Center grant RR-82 from the National Institutes of Health.

A Syndrome of Infantile CNS Degeneration

Gregory L. Holmes, MD, William J. Logan, MD

• **We describe six patients from five families, who have a syndrome that, to our knowledge, has not been previously reported. The syndrome is characterized by growth failure, ophthalmoplegia, optic atrophy, choreoathetosis, areflexia, hypotonia, dysmorphic facies, and severe mental and motor retardation. Some of the children also had microcephaly and seizures. The clinical course is remarkably uniform and slowly progressive. The abnormalities first noted are delayed psychomotor development and poor weight gain, and the others all develop within the first three years of life. The syndrome seems to be hereditary. Extensive laboratory investigation has not yielded an etiology. Until pathologic material is available, the disorder remains a syndrome and the diagnosis is established by the unique combination of neurological abnormalities.**

(*Am J Dis Child* 134:262-266, 1980)

We have had the opportunity to study six children with a previously unrecognized syndrome. Other additional cases, not examined by us, are also thought to have a similar disorder. We believe it is a hereditary disorder that is remarkably similar in manifestation and course.

REPORT OF CASES EXAMINED BY US

CASE 1.—The proposita was born at a full-term pregnancy to a gravida 2, para 1 who experienced mild nausea and vomiting in the second trimester. The parents are unrelated. The patient was related to those in cases 2 and 8 (see Fig 1). The patient was healthy at birth, but substantial delay in development was evident at age 3 months. When examined at age 4 months, she had poor control of her head, inability to roll over, hypotonia, and absent muscle stretch reflexes. The patient was not seen again until age 17 years when she was admitted to the hospital for generalized tonic-clonic seizures. At that time, she required total nursing care, and she had no intelligible speech. The patient could not walk, talk, sit without support, or feed herself. She was less than the third percentile for height, weight, and head circumference. Examination disclosed a severely retarded girl with optic atrophy bilaterally, external ophthalmoplegia, ptosis, hypotonia, absent stretch reflexes, choreoathetosis, and facial dysmorphism. Extensive laboratory studies, which were also performed in cases 3 and 6, included the following: complete blood cell count; serum electrolyte; liver function; serum magnesium; serum calcium and phosphate; serum creatinine; serum creatine phosphokinase; serum VDRL; chromosome (with banding); urine test for amino acids; serum amino acids chromatogram; thyroid function; adrenal function (hydrocortisone, adrenocorticotropic hormone-stimulation); edrophonium chloride (Tensilon); urine thiamine pyrophosphate adenosine triphosphate transferase inhibitor; immunoglobulin electrophoresis; lipoprotein electrophoresis; urine arylsulfatase; CSF for glucose, protein, cells, and IgG; serum ceruloplasmin; serum copper; urinary copper; routine urinalysis; ECG; computerized axial tomography of head; pneumoencephalogram; electromyogram (EMG); nerve conduction; muscle biopsy specimen; sural nerve biopsy specimen; and EEG. These studies disclosed no abnormalities. Her seizures are controlled by phenytoin sodium. There were several distant relatives with similar facial features, abnormal movements, and retardation, who died in infancy. Medical records of these individuals could not be obtained.

CASE 2.—The patient was born after an uncomplicated pregnancy, labor, and delivery to a 45-year-old gravida 5, para 4. The parents were unrelated. The patient is distantly related to those in cases 1 and 8

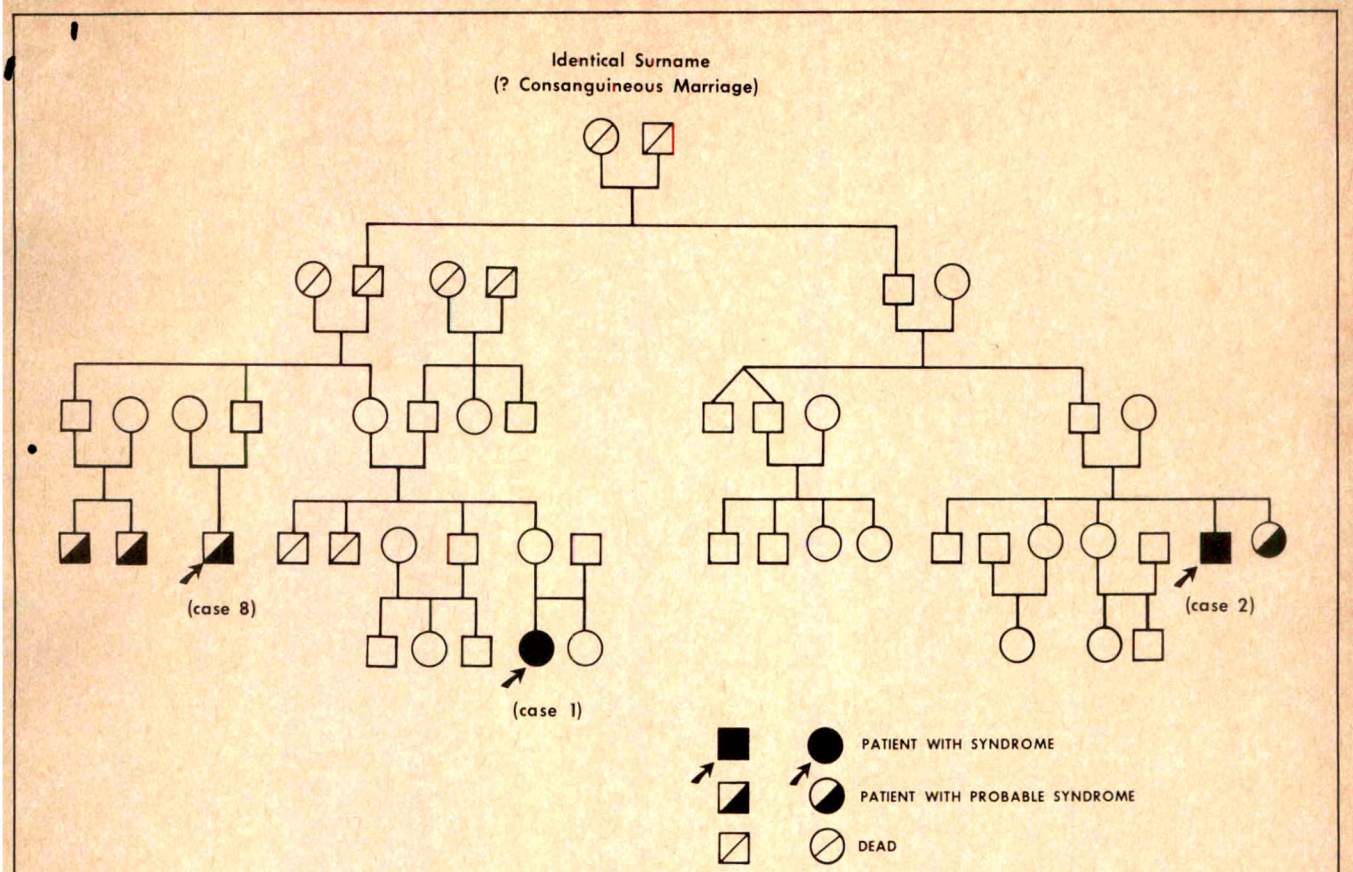

Fig 1.—Pedigree for cases 1, 2, and 8.

(see Fig 1). Because of failure to support the head and decreased muscle tone, the patient was admitted to the hospital at age 6 months for evaluation. Examination revealed normal extraocular movements, normal optic fundi, notably decreased muscle tone, areflexia, and developmental delay. Choreoathetosis was evident. The patient was seen again at age 12 years. At that time, he could not speak intelligibly, he was less than the third percentile for height and weight, and he could not walk. He required total nursing care, including feeding. There were facial dysmorphism, mild microcephaly, complete external ophthalmoplegia, ptosis, severe optic atrophy, hypotonia, areflexia, and almost continuous choreoathetosis.

Case 3.—The patient was born at a full-term, normal pregnancy, labor, and delivery to a 17-year-old primigravida who was uncertain of the father's identity. The patient was the niece of case 7. The neonatal period was unremarkable. At age 3 months, the patient had some control of her head and could roll over. However, during the next two years, she had little progression in development. She was admitted to the University of Virginia Medical Center, Charlottesville, at age 3½ years. She was unable to walk and had no intelligible speech. She was neither toilet trained nor able to feed herself, and she required total care. She was less than the third percentile for height and weight. Development was at a six-month level. There were microcephaly and mild facial dysmorphism, continuous choreoathetosis throughout waking periods, and advanced bilateral optic atrophy with sluggishly reactive pupils. She was severely hypotonic, with "frog leg" posturing of the lower extremities. During the next two years, she continued to display substantial delay in development and had major motor seizures that were easily controlled with phenytoin. She was reevaluated at age 6 years (Fig 2). Now there was total ophthalmoplegia with no movement of the eyes spontaneously or with caloric testing. As in case 1, the extensive laboratory investigations indicated no etiology for her disease.

Case 4.—This female infant was born to a gravida 3, para 2 who was not related to her husband. The pregnancy, labor, and delivery were uneventful. Developmental delay was evident during the first six months of life. The patient was examined again at age 6 years. At that time, height, weight, and head circumference were less than the third percentile. There were complete external ophthalmoplegia, ptosis, optic atrophy, mildly dysmorphic facies, hypotonia, areflexia, choreoathetosis, and severe motor and mental retardation. She could not sit, stand, or walk, and she had no intelligible speech. Since then, the patient's condition has changed little, and she requires total care (Fig 3). According to the father, there were "distant kin" with similar disorders. However, they had all died and medical records were not available.

Case 5.—This patient was born to an 18-year-old gravida 1, para 0 who denied difficulties during the pregnancy, labor, or delivery. The parents were unrelated. The immediate newborn period was normal. The child was evaluated at age 2 months because of poor head control. Hypotonia and diminished muscle stretch reflexes were found. At age 8 months, the child was admitted to the hospital for diagnostic appraisal. The child had little head control and a weak grasp, but she could roll over. She was hypotonic, with diminished stretch reflexes and choreoathetosis. She was again seen at age 6 years. She could not

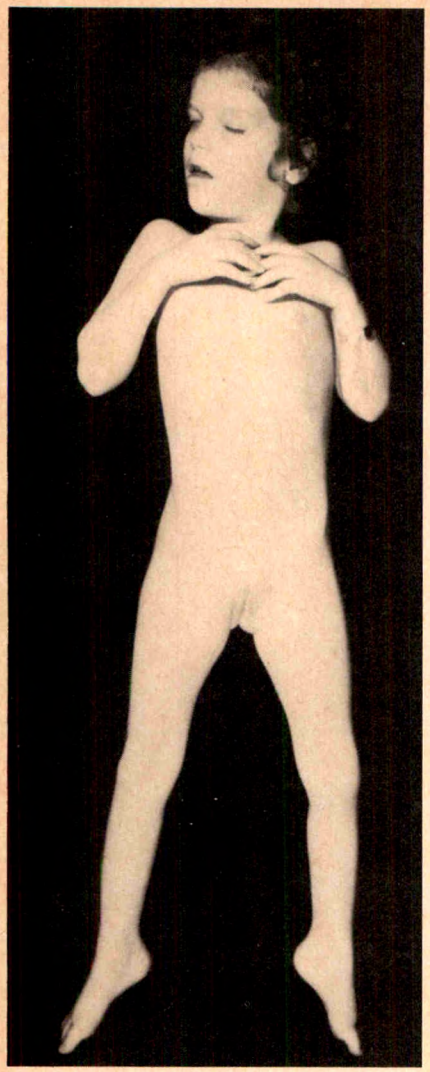

Fig 2.—Case 3, age 6 years. Note dysmorphic facies.

Fig 4.—Case 6, age 19 years. Note ptosis, dysmorphic facies, eye position.

walk or speak, and she was less than the third percentile for height, weight, and head circumference. On examination, she demonstrated choreoathetosis, hypotonia, areflexia, severe mental retardation, optic atrophy, ophthalmoplegia, and mildly dysmorphic facies. She now requires total nursing care.

CASE 6.—The patient was born at a full-term pregnancy to a healthy 28-year-old gravida 2, para 1, abortus 0. The parents were unrelated. However, the maternal grandparents were said to be distant relatives. The labor and delivery were unremarkable, and the infant was regarded as normal. Early development was delayed. She was never able to walk or speak, she never became toilet trained, and she has required total nursing care. At age 6 years, she was found to have severe hypotonia, choreoathetosis, areflexia, and optic atrophy. She was less than the third percentile for height and weight. At age 16 years, she had a generalized convulsive disorder. Examination at age 19 years disclosed microcephaly, dysmorphic facies, bilateral optic atrophy, choreoathetosis, external ophthalmoplegia, ptosis, hypotonia, and absent stretch reflexes (Fig 4). As in cases 1 and 3, the extensive laboratory investigations showed no abnormalities. She continues to have occasional seizures, and she has been receiving maintenance levels of phenytoin and phenobarbital sodium. During the past six months, there has been further deterioration, with increasing difficulty in swallowing.

MEDICAL RECORDS OF CASES NOT EXAMINED BY US

CASE 7.—This patient was the maternal uncle of case 3. The patient was born at a full-term, normal pregnancy, labor, and delivery to a 23-year-old gravida 1, para 0 who was the second cousin of her husband. The patient was believed to be normal for the first several months, and then psychomotor development slowed. At age 10 months, he was admitted to the University of Virginia Medical Center. He was less than the third percentile for height and weight. He did not vocalize and had poor head control. He had microcephaly, optic atrophy, and ptosis, and he was unable to deviate his eyes to the left. Hypotonia with diminished stretch reflexes was present. He was described as having aimless movements of his arms and fingers. The patient contracted pneumonia at age 12 months and died at another institution. Postmortem examination was not obtained.

CASE 8.—This male infant was born to a 30-year-old gravida 6, para 5 who had the same maiden name as her husband and who was thought to be distantly related to him. The pregnancy, labor, and delivery were normal. The patient was related to those in cases 1 and 2 (see Fig 1). The child did not gain head control, meaningful speech, or the ability to sit or walk. At age 4 months, he had choreoathetosis of all extremities. At age 2 years, he was admitted to the hospital for pertussis. He was less than the third percentile for height and weight. He was noted to have continuous choreoathetosis of his arms and legs. Eye movements and optic fundi were not described. However, several examiners noted poorly reactive pupils. The child died of pneumonia. At postmortem examination, the child had evidence of diffuse bilateral pneumonia. The brain seemed normally developed, without any gross abnormalities. There was some meningeal congestion, and on microscopic examination, atrophy of the cortex and cerebellum was noted.

RESULTS

The Table summarizes the remarkably similar histories and signs that we have found in these eight unfortunate children. The malady seems to start early in infancy after an uneventful pregnancy, labor, and delivery. Early developmental delay is soon evident, with all being severely retarded and none being able to walk, speak intelligibly, or care for bodily

needs. Eye movements were normal initially with ophthalmoplegia beginning after age 3 years in all children except patient 7, who was found to have ophthalmoplegia at age 10 months. The ophthalmoplegia is complete, with no reflex movements. Optic atrophy seems to be a late finding, with the earliest detection being at 10 months, again in case 7. Unfortunately, the exact time of appearance of optic atrophy is difficult to estimate because of infrequent examinations in most of these children. Dysmorphic facies were present to a certain degree in all the patients examined by us, with the characteristic features of a wide nasal bridge, small mandible, and prominent maxilla. Figures 2 and 3 (cases 3 and 4) show patients with mild facial dysmorphism whereas Fig 4 (case 6) shows a patient with a severely dysmorphic face. All of our patients, in addition, had choreoathetosis, growth failure, and hypotonia early in the course. Microcephaly occurred in four patients and, when present, was mild. Seizures of various severity occurred in five. The seizures developed late in the course of the disease and tended to be generalized tonic-clonic seizures and, thus far, have been easily controllable.

The movement disorder occurs within the first year. It is bilateral, involving both the upper and lower extremities and disappearing with sleep. There does not seem to be any worsening of the movement disorder with age. One patient (case 6) was given a trial dose of a carbidopa-levodopa mixture, with no improvement in the choreoathetosis.

Several observations suggest that the disorder is inherited in an autosomal recessive pattern. Two of the patients examined by us (cases 1 and 2) and one other child not examined by us (case 8) were distantly related (Fig 1), and in several other families, there was a history of similarly affected children although this could be documented in only one additional family (cases 3 and 7). Although the families could not all be linked directly, the geneology of each patient included an identical surname. Consanguinity was frequent (all the family pedigrees are available on request from the authors).

Laboratory investigations were not helpful in determining the etiology of the disorder in our patients. Diagnostic studies done are listed in the report of case 1. Three patients (cases 1, 3, and 6) were studied extensively and had received all of the aforementioned tests except the muscle and nerve biopsy specimens, which were performed in case 1 only.

The disorder seems to be slowly progressive. The older patients in the series (ages 19 and 21 years) have changed little in the past six years. None of the patients examined by the authors have died, and brain tissue, therefore, has not been available. One patient, who was not seen by the authors (case 8), had only microscopic evidence of cortical and cerebellar atrophy at the time of death. Since a funduscopic examination was not done and eye movements were not described, we are unsure of whether this patient had the syndrome.

COMMENT

In the differential diagnosis, there are many syndromes that have some of the findings of the patients described. A brief review of syndromes that may be confused with our cases will be presented.

Seitelberger[1] in 1952 reported a previously undescribed syndrome that was characterized by onset before the second year of life, progressive psychomotor deterioration, hyperkinetic movements, hypotonia, limb and cranial nerve palsies, and optic atrophy. There is considerable controversy in the literature as to whether this disease is a variation of Hallervorden-Spatz disease or a separate disease, described by some authors as infantile neuroaxonal dystrophy.[2-6] The patients described in this report differ

from those with the varieties of Hallervorden-Spatz disease and infantile neuroaxonal dystrophy, primarily by the notable ophthalmoplegia.

Pelizaeus-Merzbacher disease has many of the characteristics of this syndrome.[7,8] The syndrome occurs in male subjects who are afflicted with a slowly progressive form of cerebral diplegia with the onset during infancy of nystagmus, poor head control, microcephaly, optic atrophy, spasticity, and growth failure. The syndrome is slowly progressive. Unlike our children, choreoathetosis and ophthalmoplegia are not consistent features in the Pelizaeus-Merzbacher syndrome.

Two other disorders that are similar to our syndrome include Krabbe's disease and Bassen-Kornzweig disease. Krabbe's disease is manifested by retardation of motor development, spasticity, seizures, optic atrophy, and the pathologic finding of globoid cells in the brain with a deficiency of galactocerebroside β-galactosidase.[9,10] Bassen-Kornzweig disease is characterized by a betalipoproteinemia, hypocholesterolemia, fat malabsorption, acanthocytosis, ataxia, chorea, nystagmus, weakness, muscle atrophy, peripheral neuropathy, and retinitis pigmentosa.[11] In neither of these syndromes is ophthalmoplegia a component. Multiple syndromes occur with ophthalmoplegia.[12] However, none bear an overall resemblance to the patients described.

On a clinical basis, our syndrome anatomically involves the cerebrum diffusely, with particular involvement of the optic nerves and basal ganglia. The hypotonia is probably on a central basis in view of the normal nerve conductions, EMG, and nerve and muscle biopsy specimens. Cerebellar involvement is difficult to assess because of the severe hypotonia, ophthalmoplegia, and choreoathetosis. The anatomical localization of the ophthalmoplegia remains unclear. As emphasized by Berenberg et al[13] and Rowland,[14] the disorder may reside in the ocular muscles, neuromuscular junction, cranial nerve nucleus, or supranuclear connections. Since pathologic specimens are not yet available, we cannot say definitely where the lesion is located. Until the time that pathologic material becomes available, the disorder remains a syndrome characterized by a unique combination of neurological abnormalities beginning during childhood.

Heart Failure in Cystic Fibrosis

Treatment and Prognosis of Cor Pulmonale With Failure of the Right Side of the Heart

Robert C. Stern, MD; Gordon Borkat, MD; Stephen S. Hirschfeld, MD; Thomas F. Boat, MD; LeRoy W. Matthews, MD; Jerome Liebman, MD; Carl F. Doershuk, MD

• **Failure of the right side of the heart with cardiac dilation and fluid retention occurred in 55 of 170 patients who died of cystic fibrosis; six patients survive. All had severe hypoxia, but 24% had normal $Paco_2$. Cardiac catheterization showed high mean pulmonary artery pressure and resistance. Pulmonary artery wedge pressure was greater than 12 mm Hg in 40% of the patients. Mean survival was eight months. Male survival was significantly better than female survival. Digitalis treatment was of no clear benefit. Tolazoline hydrochloride was also ineffective. Recent medical advances have not substantially affected prognosis.**

(*Am J Dis Child* 134:267-272, 1980)

Chronic alveolar hypoxia is largely responsible for the pulmonary hypertension[1,2] and resultant right-sided heart disease (cor pulmonale) that occur in the course of a variety of chronic pulmonary diseases.[2] Ultimately, overt right-sided heart failure with cardiac dilation and fluid retention may occur, and this seems to accelerate the deterioration of the patient's condition. This has been an increasingly common event in patients with cystic fibrosis[3-6] as increasing numbers of persons with this disease survive to young adulthood and later.[3,7] The recognition and treatment of this complication has received increased attention recently, and routine medical therapy including salt restriction and diuretics have generally been accepted as effective. The use of digitalis is more controversial,[8] and the more recently advocated vasodilator, tolazoline hydrochloride,[9] has not been adequately investigated.

We present here our experience with overt right-sided heart failure complicating cystic fibrosis. A total of 61 patients including 30 for whom cardiac catheterization data are available are described. The data suggest that the prognosis for this complication remains grim despite the continued use of salt restriction, the addition of more potent diuretic agents, and the use of digitalis and tolazoline.

From the Divisions of Pediatric Pulmonary Disease (Drs Stern, Boat, Matthews, and Doershuk) and Pediatric Cardiology (Drs Borkat, Hirschfeld, and Liebman), Case Western Reserve University, School of Medicine, and Rainbow Babies and Childrens Hospital (Drs Stern, Borkat, Hirschfeld, Boat, Matthews, Liebman, and Doershuk), Cleveland.

Reprint requests to Rainbow Babies and Childrens Hospital, 2101 Adelbert Rd, Cleveland, OH 44106 (Dr Stern).

PATIENTS AND METHODS

The charts and chest roentgenograms of all patients with cystic fibrosis who have been seen at this center were reviewed. Cystic fibrosis was diagnosed by an abnormal sweat test in addition to either typical pulmonary or digestive symptoms or a family history of the disease.

The following criteria were used for the diagnosis of overt right-sided heart failure: (1) a 1.1-cm or greater increase in the size of the cardiac silhouette on sequential, standard posteroanterior chest roentgenograms during a period not exceeding six months; and (2) evidence of fluid retention (ie, a tender, enlarged liver and/or peripheral edema and/or ascites). Weight gain alone was not considered sufficient to establish fluid retention. Only patients who survived longer than two weeks after these initial criteria were met are included.

The clinical status of the patients, cardiac catheterization data, ECG data, pulmonary function data, and arterial blood gas determinations at the onset of overt right-sided heart failure were analyzed. The subsequent course of the patients' conditions with respect to treatment, additional complications, and survival are reported.

Patients undergoing cardiac catheterization received no sedation or other medication prior to the procedure. Pressure measurements were made using standard fluid-filled catheters and a physiologic pressure transducer and were recorded on a physiologic recorder. The zero level for pressure measurements was the midchest. Cardiac output was measured by a cardiogreen dilution technique[10] in 28 patients and by the Fick principle[11] in two patients.

Vectorcardiograms were obtained using the Frank system.[12] Echocardiograms were

recorded with an ultrasonoscope interfaced with a multichannel physiological recorder. Right and left ventricular dimensions were recorded from a standard position along the left sternal border. Measurement of right and left ventricles were made in end-diastole at the onset of the QRS complex. When aortic and pulmonic cusps could be recorded echographically, systolic time intervals were measured.[13]

Pulmonary function tests were performed by standard spirometric and plethysmographic techniques.[14-16] Blood gas analyses were performed by the clinical laboratory. Where appropriate, Student's *t* test for unpaired variables was used for statistical analyses.

RESULTS

Clinical Status

A total of 61 (8.3%) of the 728 patients seen at this center during a 20-year period had overt right-sided heart failure secondary to cystic fibrosis. The clinical status of the patients at onset of right-sided heart failure is summarized in Table 1. Only six of the 61 patients did not have liver tenderness and enlargement, whereas 22 (36%) did not have peripheral edema. Abnormal weight gain was absent in 38 patients; many patients, in fact, had lost weight since the time of their previous examination. Five patients had the typical murmur of tricuspid insufficiency develop either simultaneously with or shortly after the onset of cardiac dilation and fluid retention.

Data Analysis

Pulmonary function testing showed a consistent abnormality in the ratio of the residual volume to total lung capacity (RV/TLC), indicating severe obstructive disease. All patients had a value of 0.60 or greater (range, 0.60 to 0.85; mean, 0.70). Other pulmonary function results, although generally extremely abnormal, were less consistent. Vital capacity, for example, ranged from 21% to 68% of the predicted value for height, and the forced expiratory volume at one second (FEV_1) ranged from 17% to 74% of the vital capacity.

Arterial blood gas measurements showed consistent and severe hypoxemia (Pao_2 ranged from 18 to 49 mm Hg; mean, 35 mm Hg); but carbon dioxide tension was somewhat more

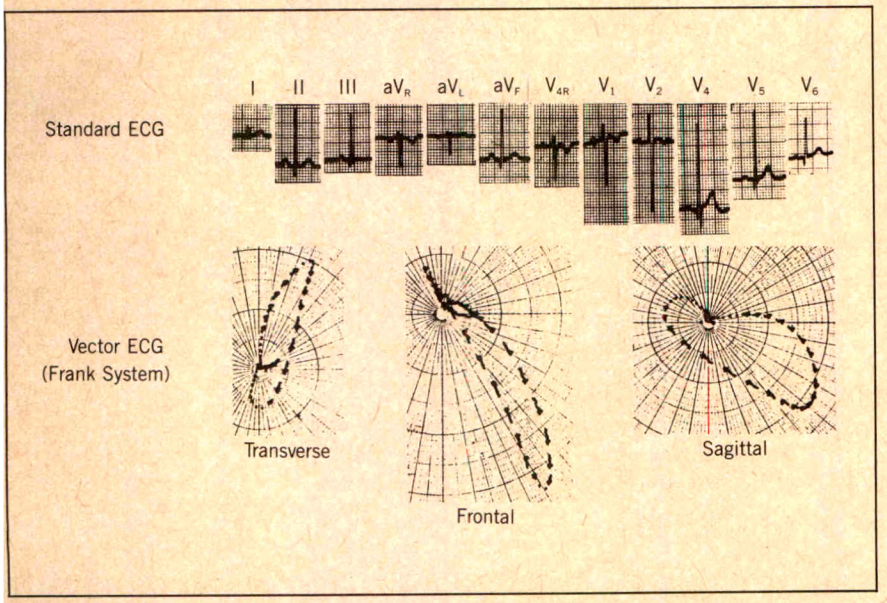
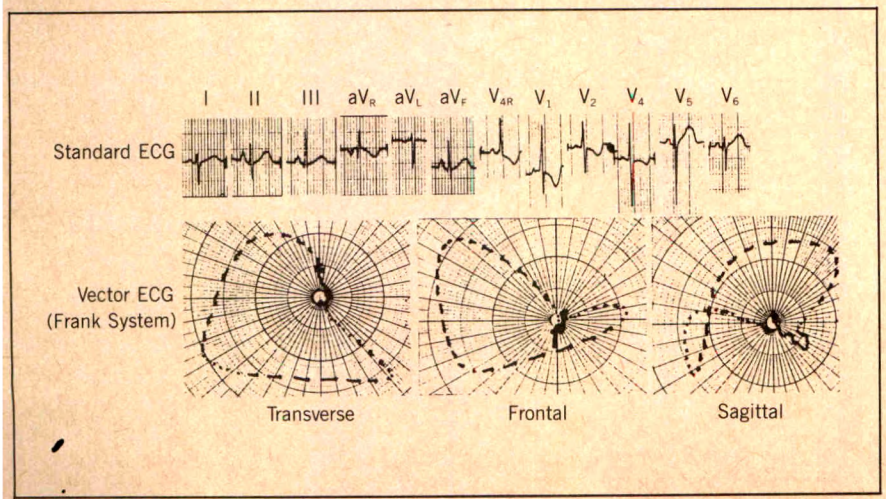
*Vital capacity is reported as percent of that predicted for height. RV indicates residual volume; TLC, total lung capacity; plus sign, present; minus sign, absent.
†Patient is alive as of Jan 1, 1979. Other patients have died.



Standard ECGs and vectorcardiograms for patients 40 (top) and 1 (bottom). Patient 40 has normal studies despite mean pulmonary artery pressure of 45 mm Hg and mean right atrial pressure of 10 mm Hg. Patient 1 has definite right ventricular hypertrophy despite generally milder, and presumably shorter duration, cardiovascular abnormality.



variable (range, 30 to 76 mm Hg; mean, 53 mm Hg), with 12 (24%) of the 51 patients for whom blood gas data were available having values less than 46 mm Hg.

Standard ECGs generally showed right ventricular hypertrophy (40 cases or 66%) and often showed right atrial hypertrophy (20 cases or 33%). Other findings included left ventricular hypertrophy, ST and T wave abnormalities, and low voltage. Six patients had completely normal ECGs. The top part of the Figure demonstrates this in one patient (patient 40), whose cardiac catheterization showed a mean pulmonary artery pressure of 45 mm Hg and a mean right atrial pressure of 10 mm Hg. His vectorcardiogram (Figure, top) was also normal. In other patients, vectorcardiographic abnormalities included right ventricular hypertrophy and abnormal posterior vector. The bottom part of the Figure illustrates both an extremely abnormal standard ECG and vectorcardiogram in a 3-year-old girl (patient 1), whose cardiac catheterization data was less abnormal than that of patient 40 (Figure, top). Echocardiographic measurements were generally more helpful in predicting ventricular size (by measurement) and in predicting diastolic pulmonary artery pressure (by assessment of the systolic time intervals).

Cardiac catheterization data for the 30 patients who had the procedure done are given in Table 2. There was considerable variation in the right atrial pressure (range, 1 to 29 mm Hg) at the onset of cardiac dilation; four patients (patients 12, 13, 46, 49) had normal or near-normal values. Although pulmonary artery pressure was invariably elevated, the range at onset of right-sided heart failure was considerable (28 to 70 mm Hg). The pulmonary artery wedge pressure was elevated (greater than 12 mm Hg) in 12 (40%) of the 30 patients.

Therapy

All patients were treated with low salt diet and diuretics. Diuretic therapy was intravenous (IV) initially (mercurial agents used with aminophylline or, more recently, ethacrynic acid, or furosemide). Many patients

received oral spironolactone or triamterene. Routine therapy for cystic fibrosis including pancreatic replacement at mealtime, supplemental vitamins, aerosols containing phenylephrine and/or isoproterenol hydrochloride, and oral antibiotics was continued. All patients also were treated intermittently with high-dose IV or intramuscular antibiotics. The use of digitalis was based mainly on the physician's preference rather than on any particular clinical finding. Tolazoline was used if a decrease in pulmonary arterial resistance with this agent had been demonstrated at cardiac catheterization or, for some patients who were not catheterized, if they had failed to respond to other measures for congestive heart failure.

Outcome

Survival data (Table 1) indicate a mean survival of eight months (median, four months; range, one month to 63 months) after onset of cardiac dilation and fluid retention; 39 (63%) of the 61 patients had died by six months, and 49 (80%) by 12 months. Three male patients have the longest survival (47 to 63 months); the longest survival by a female patient was 28 months. Male survival (mean, 12 months) was significantly longer ($P < .05$; unpaired t test) than that of female patients (mean, six months). There was no statistically significant difference in survival for patients during the five-year period from 1974 to 1979 (mean, 8.1 months) compared with those whose onset of cardiac dilation preceded 1974 (mean, 9.6 months).

Digitalis was used in 47 patients and their mean survival (8.0 months) was not significantly different from that of the 14 patients who did not receive digitalis (10.7 months). Tolazoline hydrochloride (1 mg/kg/dose, twice a day, intravenously) was given for at least one three-week course to 32 patients. Survival (mean, 9.1 months) was not significantly different from those patients who did not receive this treatment (mean, 8.3 months).

The five patients with the longest survival (greater than two years) were not, as a group, different from the remainder of the patients with regard to any of the clinical or laboratory findings reported here except that they were somewhat older. (Mean age of 20 years was compared with overall mean age of 16½ years for the remaining 56 patients.)

Autopsy data were available for 37 of the 51 patients who died in the hospital. All had right ventricular hypertrophy, and 19 had unequivocal right ventricular dilation; 13 had left ventricular dilation, and six had defi-

*The decreasing numbers for successive age groups in the categories of patients seen at this center reflect losses owing to death and lack of follow-up for total number of 728 patients.

nite right atrial dilation. Three patients had focal myocarditis. All patients had extremely severe pulmonary involvement with bronchiolectasis and extensive destruction of pulmonary parenchyma. Eight patients (21%) had the typical biliary cirrhosis of cystic fibrosis. None of the patients had had clinical symptoms of hepatic disease.[17]

Of 170 patients who have died at this center, 55 (32%) are reported here to have had overt right-sided heart failure at least two weeks prior to death (six patients survive). The age-related and sex-related incidence rates among all patients seen at this center are presented in Table 3. There is a trend toward increasing incidence of overt right-sided heart failure with increasing age.

Two patients (patients 17, 37) required general anesthesia for surgical complications of cystic fibrosis after onset of overt right-sided heart failure. One (patient 37) had a pneumothorax develop nine months after cardiac dilation. Her condition failed to improve with supportive measures, and she finally had an open thoracotomy with total pleural abrasion and apical pleurectomy.[18] She is still alive 18 months after onset of right-sided heart failure and nine months after the thoracotomy. The other patient (patient 17) required operative intervention for recurrent (more than five episodes) intussusception and had a laparotomy when nonsurgical procedures were unable to effect reduction. Postoperatively, intussusception did not recur, but the patient died of respiratory failure two weeks later.

Virtually every patient was completely disabled after onset of overt right-sided heart failure although two (patients 52, 54) did return to full-time employment and continued to work for several months. Most patients required hospitalization frequently and for prolonged periods. On the average, after onset of cardiac dilation, 26% of the remainder of the patient's life was spent in the hospital.

COMMENT

Overt right-sided heart failure with cardiac dilation has become an increasingly common complication of the pulmonary lesion of cystic fibrosis as mean life expectancy for patients with this disease has been extended.[3] Our data (Table 3) suggest that this trend will continue. Whereas only 21% of our patients who died at 14 years or younger had this complication, 46% of those who died at 15 years or older did have overt right-sided heart failure at least two weeks prior to death. Similar results are obtained when the incidence of overt right-sided heart failure in patients who remain alive at various ages is examined (Table 3). Possibly, the older patients are exposed to more sustained and severe hypoxemia that permits the development of severe and unrelenting pulmonary hypertension.

At the onset of cardiac dilation, the great majority of patients had enlarged, tender livers, but only 64% had detectable peripheral edema. Ascites was rare. Interestingly, only 22 (38%) had demonstrable weight gain since their previous hospitalization or clinic visit. Many, in fact, had lost weight. The most probable reason for this is that the ongoing weight loss of chronic disease had exceeded the weight gain from fluid retention. In any case, however, the absence of weight gain should not be considered as evidence that a patient with cystic fibrosis does not have right-sided heart failure.

Arterial blood specimens, available for 51 patients, confirmed the relationship of right-sided heart failure to severe hypoxia.[1] All Pao_2 values were less than 50 mm Hg (mean, 34.8; SD, 8.3). Some patients were extremely hypoxemic, with 27 having values less than 35 mm Hg. Five patients were so well compensated to chronic hypoxemia that they were able to walk into the hospital with Pao_2 values ranging from 18 to 25 mm Hg. Hypercarbia was apparently of far less importance in that almost 25% of the patients had normal or near normal values.

Although severe hypoxemia was a constant finding, there was considerable variability in pressure and resistance data obtained at cardiac catheterization (Table 2). Some patients had normal right atrial pressures and cardiac outputs. These findings do not rule out congestive failure, which exists when cardiac output is unable to meet metabolic needs of the body. In addition, these tests were performed at rest; any additional activity might have changed the findings considerably. By contrast, however, other patients did not have overt heart failure develop until much more severe abnormality in the pulmonary circulation had developed. The reason for these individual differences is not clear.

Standard pulmonary function findings included a consistent and severely abnormal RV/TLC ratio. The vital capacity, although abnormal, did

not show as close a correlation with mean pulmonary artery pressure or with pulmonary vascular resistance as expected. For example, one patient (patient 48) with a vital capacity of 60% of that predicted had a mean pulmonary artery pressure of 60 mm Hg, whereas another (patient 56) with a vital capacity of 25% of that predicted had a mean pulmonary artery pressure of only 40 mm Hg.

Standard ECG and vectorcardiographic findings were not closely correlated with pulmonary vascular resistance or mean pulmonary artery pressure. Echocardiography, however, was useful if systolic time intervals could be obtained. In addition, the echocardiogram has been able to differentiate those patients with left ventricular dysfunction from those with "pure" right ventricular failure. This may prove important in the selection of patients for catheterization and in the determination of which studies should be performed.

The data confirm the grim prognosis for patients who have overt right-sided heart failure develop.[4-6] Mean survival was only eight months and has not been substantially affected by recent, more aggressive medical management. The survival for the past five years is not better than for the preceding 15 years. Similarly, digitalis does not seem to offer any substantial benefit to the majority of these patients, with survival rates in those treated (mean, eight months) similar to those not treated (mean, ten months).

Recently, tolazoline has been reported to lower mean pulmonary arterial resistance and pulmonary artery pressure.[9,19,20] Although initial results with clinical use seemed favorable,[19,20] we now report that, in this substantially larger group of patients, this drug does not seem to have any clear-cut effect on survival. There is little doubt, however, that short-term use of diuretics resulted in subjective improvement and we have shown previously[21] the effectiveness of IV diuretics for heart failure by measurements of right atrial pressure. All patients in this series received treatment with diuretics and low salt diet.

The somewhat better course in male patients is not easily explained but is consistent with the widely reported better prognosis for male subjects, both in individual centers[7] and from analysis of cooperative national statistics.[22] All three patients who survived longer than three years were male as was one patient reported elsewhere.

Our data suggest that future assessment of treatment measures for overt right-sided heart failure in cystic fibrosis including tolazoline, low-flow oxygen, prophylactic digitalis, or low salt diet must include appropriate control patients. Left ventricular unloaders would also seem to deserve a trial in selected patients. An effective approach to this complication is urgently needed, as demonstrated by our dismal survival statistics.

Nonketotic Hyperglycinemia

Effects of Therapy With Strychnine

David Warburton, BSc, MB, MRCP; Robert J. Boyle, MD; John P. Keats, MD; Betty Vohr, MD; Siegfried Peuschel, MD; William Oh, MD

• Nonketotic hyperglycinemia was diagnosed in identical twins with lethargy and respiratory failure in the neonatal period. Therapy with strychnine (0.32 mg/kg/day) resulted in great reductions in CSF and plasma glycine levels and improvement in muscle tone, respiration, and ability to suck. Myoclonic seizures were partially controlled by therapy with clonazepam. Higher dosages of strychnine (up to 2.0 mg/kg/day) were needed to counteract the increased lethargy following administration of clonazepam. At 5 months of age, the twins' developmental performance remained below the 1-month level despite adequate somatic growth. The twins died suddenly of status epilepticus at 6½ months of age.

(*Am J Dis Child* 134:273-275, 1980)

Nonketotic hyperglycinemia (NKH) is a rare, inherited disorder of glycine metabolism characterized by muscular hypotonia, myoclonic seizures, mental retardation, and early death.[1] Glycine levels in plasma may be elevated up to three times normal and large amounts of glycine are excreted in the urine. The poor prognosis in this disorder has been attributed to absence of both hepatic and cerebral glycine cleavage enzyme activity.[2] Defective oxidation of glycine to serine[3,4] results in glycine accumulation in CSF with levels 15 to 30 times normal and a glycine content two to four times normal in several brain regions.[2]

Previous therapeutic approaches with this disorder have included restriction of dietary glycine intake; administration of compounds potentially active in replenishing the pool of single carbon units; supply of the coenzyme precursor pyridoxine; and administration of glycine-binding agents.[5-9] Glycine levels in plasma were lowered in one patient who was treated with sodium benzoate and a ventriculoperitoneal shunt[9]; however, CSF glycine concentrations remained unchanged. None of these treatments have effectively prevented mental retardation, even when instituted in the neonatal period.[9]

Glycine is thought to act as an inhibitory neurotransmitter in the brain stem, in the spinal cord, and in some neurons in higher centers.[10-13] Strychnine has high affinity for glycine receptors[12-14] and therefore acts as a glycine antagonist. Gitzelman and others[15-17] have reported treatment of NKH with strychnine.

Therapy with strychnine was used for NKH in identical twin boys in whom the condition was diagnosed in the neonatal period. The effects of therapy with strychnine were followed with monitoring of serial plasma and CSF glycine levels. Changes in activity and development of the two infants were also evaluated.

REPORT OF CASES

One pair of twins (both male) were the product of a 40-week gestation in a 20-year-old, gravida 1, para 1, blood type O, Rh-positive mother. The prenatal course was unremarkable and fetal activity had been normal. An elective cesarean section was carried out at term for malpresentation in a twin gestation. Baby A weighed 2,550 g, was delivered from a transverse lie, and had Apgar scores of 7 and 9 at ages 1 and 5 minutes, respectively. Baby B weighed 2,650 g, was delivered by the breech, and had Apgar scores of 7 and 9 at ages 1 and 5 minutes, respectively. The placenta was monochorionic-diamniotic. Blood subgrouping showed that the twins were Rr, M−, N+, P+, L−, Duffy A−, S−. This, together with the placental findings, confirmed that the twins were identical. The family history showed no metabolic, neuromuscular, or CNS diseases. The infants were normal initially, but increasing lethargy was noted over the first three days of life. Eventually, both infants required gavage feeding and did not cry after circumcision. Some minor tremors of the limbs but no overt seizure activity was noted. The infants were referred to Women and Infants Hospital of Rhode Island, Providence.

On admission, the twins were flaccid and did not react to painful stimuli. Their vital

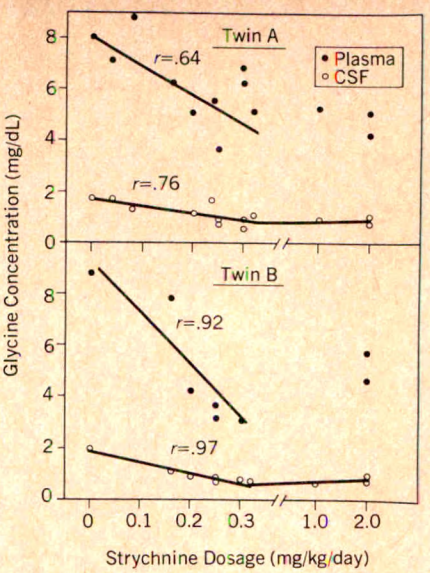
signs and measurements were as follows: twin A, temperature was 37.3 °C, pulse rate was 136 beats per minute, respirations were 36/min, weight was 2,435 g, head circumference was 33 cm, length was 49 cm; twin B, temperature was 36.3 °C, pulse rate was 150 beats per minute, respirations were 44/min, weight was 2,600 g, head circumference was 33 cm, length was 52 cm. Both twins were normocephalic with normal anterior fontanels. They did not open their eyes spontaneously; however, a normal red reflex was elicited and a doll's eye reflex was present. Rooting reflex was absent. Sucking and gag reflexes were poor. Moro's reflex was absent. No fasciculations were seen. Deep tendon reflexes were present; they were reduced in the upper extremities and hyperreflexic in the knees and ankles. Plantar reflexes were unresponsive. There were no external congenital anomalies, and the results of the remainder of the examination were normal. Within 48 hours of admission, progressive respiratory failure developed in both infants, requiring assisted ventilation.

Complete blood cell count and serum electrolyte, glucose, calcium, phosphorus, magnesium, bilirubin, protein, BUN, arterial pH, and blood gas levels were within normal limits. Results of lumbar puncture showed normal CSF.

Skull and chest roentgenogram, electromyogram, and muscle biopsy specimens were normal. Electroencephalogram showed a quiet sleep pattern with bursts of sharp wave activity that were thought to be paroxysmal in nature. There was no improvement in muscle tone with administration of edrophonium chloride (Tensilon). Urine, blood, and CSF organic acid, mucopolysaccharide, and amino acid levels were normal except for the glycine level, which was sharply elevated (Figure). Glycine was measured in serum and CSF using column chromatography on an amino acid analyzer. In the absence of acidosis, a diagnosis of NKH was made on the basis of markedly elevated glycine levels in both plasma and CSF (Figure).

Informed consent having been obtained from the parents, therapy with oral strychnine was instituted at a dosage of 0.04 mg/kg/day divided into six hourly doses. The dosage was increased every 48 hours until the twins were breathing well enough to be extubated. On the tenth day of therapy with strychnine, both infants had seizures and their strychnine dosage was reduced from 0.3 mg/kg/day to 0.2 mg/kg/day. However, it was necessary to increase the dosage again to 0.3 mg/kg/day and then to 0.32 mg/kg/day to facilitate sucking. The twins went home on day



Plasma and CSF glycine concentrations relative to the dosage of strychnine given to twins with nonketotic hyperglycinemia. Normal ranges for children 1.3 months old: Level of glycine in plasma, 0.79 to 1.67 mg/dL; level of glycine in CSF, 0.022 to 0.078 mg/dL.

34 of therapy with strychnine and required only occasional gavage feedings. Their weight at the time of discharge was 2,945 g and 3,190 g, respectively. They were seen daily by a visiting nurse and were seen weekly in our follow-up clinic.

Two weeks after discharge, the twins exhibited excessive myoclonic jerking. Their strychnine dosage was reduced to 0.25 mg/kg/day. However, two weeks later, the weight of each twin was reduced 500 g, increasing lethargy developed, respirations slowed to 20 and 24/min, respectively, and they were readmitted to the hospital. The strychnine dosage was increased stepwise to 1.0 mg/kg/day with a concomitant improvement in respiratory rate and resumption of sucking. Electroencephalograms showed a hypsarrhythmia pattern in both twins. Administration of clonazepam was begun at a dosage of 0.01 mg/kg/day and was increased slowly to 0.2 mg/kg/day. Myoclonic jerks became less prominent. However, the infants became more lethargic and did not suck as well while receiving clonazepam. The strychnine dosage was increased stepwise to 3.0 mg/kg/day with improved sucking and muscle tone. Generalized seizures developed in twin B at this dosage and so the strychnine dosage for both twins was reduced to 2.0 mg/kg/day. They were sent home receiving this dosage divided every four hours, the clonazepam being given before meals and the strychnine afterwards. Weight gain and head growth were maintained along the fifth percentile.

Neurologically, at 5 months of age, the infants had normal muscle tone, but with marked strabismus and occasional myoclonic jerks. Neither infant was able to focus his gaze because of strabismus. Both infants managed an occasional smile and they raised their heads infrequently; they functioned below the 1-month level.

COMMENT

Therapy with strychnine resulted in a fall in plasma and CSF glycine levels in these identical twin males with NKH, and a concomitant improvement was seen in the muscle tone and the level of consciousness (Figure). However, despite early diagnosis (18th day of life) and the use of increasing dosages of strychnine (up to 2.0 mg/kg/day), the developmental prognosis for the infants remained poor and the plasma and CSF glycine levels remained elevated within the range of mild NKH as recently reported by Frazier et al.[18] The toxic-therapeutic ratio of strychnine dosage seems to be narrow since at a dosage of 0.15 mg/kg/day, these infants were too lethargic to suck and at 3.0 mg/kg/day, generalized convulsions developed in twin B.

It is likely that the beneficial effect of strychnine on muscle tone and level of consciousness in NKH is due to the antagonism of excessive glycine-mediated postsynaptic inhibition.[10,13,19] However, the role of strychnine-glycine interactions in the underlying hypsarrhythmic seizure disorder in the twins and in other infants[15] is not clear. Strychnine and glycine bind to different sites at the glycine receptor, so that only part of the strychnine bound to nervous tissue membranes is displaced by glycine.[20] Strychnine also reduces the in vitro binding of β-alanine to synaptosome-enriched fractions of rat brain.[21] Hence, the effects of strychnine in vivo are probably not solely due to reduction of glycine-mediated postsynaptic inhibition.

Clonazepam, a derivative of medazepam (Benzodiazepine) hydrochloride, was useful in controlling excessive strychnine-induced myoclonic jerks associated with the hypsarrhythmic seizure disorder seen in these infants. It has been suggested that

benzodiazepines act on glycine receptors and thereby interfere with strychnine binding[22]; however, this mechanism remains controversial.[23,24]

Although strychnine produced a remarkable improvement in hypotonia, respiratory drive, and sucking activity in the twins, which was correlated with concomitant reductions in plasma and CSF glycine levels, their plasma and CSF glycine levels remained elevated and their neurologic functions did not become normal. Moreover, their strychnine dosage had to be adjusted frequently and the drug may have exacerbated their underlying hypsarrhythmic seizure disorder. However, the improvement in respiratory and feeding functions did allow us to discharge the patients and the parents were able to care for them at home.

The twins died suddenly of status epilepticus within 15 minutes of each other at 6½ months of age. They had been admitted to the hospital prior to further metabolic studies. We suspected a medication error. However, concentrations of strychnine in the blood and urine of both twins measured at the time of autopsy were as follows: twin A, blood, 0.44 mg/dL, urine, 0.18 mg/dL; twin B, blood, 0.38 mg/dL, urine, 0.12 mg/dL.

These levels are within the toxic range but below the lethal range reported in adults.[25] There are no data for infants or children. Important autopsy findings were limited to the brain. Both cases showed microvacuolization of white matter and diffuse gliosis of the gray matter. One twin had hypoplasia of the corpus callosum and slight hydrocephalus. The cause of death may have been related to their medication or to an underlying seizure disorder. Results of developmental testing within one week of death showed that both twins were functioning below the 1-month level.

Mary Ann Ampola, MD, performed the glycine determinations.

Renal Venous Thrombosis in Neonates

Initial and Follow-up Abnormalities

Madjid Rasoulpour, MD, Robert H. McLean, MD

• **Five neonates with renal venous thrombosis (RVT) were studied at the onset of the disease, and four have been followed up for from 24 to 32 months after the time of diagnosis. Reduced glomerular filtration (two of four cases) on follow-up occurred only in infants with bilateral abnormalities as shown by results of physical examination, urography, renal scan, and angiography. Results of contrast studies showed the similarity between resolved RVT and certain congenital renal abnormalities. Renal tubular defects (polyuria, acidosis, hyperkalemia) constituted the primary clinical abnormalities in one of the two infants with renal insufficiency. Although the prognosis of RVT after medical management has improved, the ultimate outcome is unknown; the possibility of unsuspected neonatal RVT should be considered during investigation of children with unilaterally or bilaterally small kidneys.**

(*Am J Dis Child* 134:276-279, 1980)

Renal venous thrombosis (RVT) is suspected in a patient, particularly a neonate, in whom hematuria and an enlarged kidney develop shortly after a period of asphyxia, shock, dehydration, or sepsis.[1-3] The suggestion has been made that RVT is a bilateral disease but with asymmetrical involvement, such that a minor lesion in the less-involved kidney might be overlooked.[4] The thrombosis commonly begins in the interlobular or arcuate veins of the kidney and less commonly in the main renal vein. The thrombosis may spread retrograde to involve the cortex or may extend inward to the main renal veins and the inferior vena cava. As the result of venous obstruction, infarction and hemorrhage occur and blood leaks into the interstitium and tubules, which may result in fibrosis.

A number of factors seem to be related to the pathogenesis of RVT. Dehydration has been implicated as the most common cause in infants and newborns.[4-6] The infants of diabetic mothers have an increased susceptibility to RVT[7,8] and children with congenital heart disease who have had angiographic studies are also susceptible to RVT.[4]

During a two-year period, we have cared for five neonates with RVT. The initial and subsequent evaluation and therapy of these patients are the subject of this report.

PATIENTS

Initial Evaluation

One infant was born to a class B diabetic mother; the mothers of the other four infants were all in good health. All the neonates were male and three were preterm. Grunting and retraction developed in case 2 during the first hour of life and a chest roentgenogram showed a diffuse reticulogranular pattern and air bronchograms. Results of an initial blood determination showed acidemia and subsequent determinations showed hypoxemia and hypercapnea and continued acidemia. This patient required respiratory support for seven days. Case 4 was delivered by low forceps; after intubation, his condition improved immediately and he was extubated after ten minutes. Case 5 was also delivered by low forceps and there was abruptio placentae with an estimated maternal blood loss of 1,000 mL. Extubation was performed after four hours.

Cultures of blood, urine, and CSF were performed in three neonates (cases 2, 4, and 5) during the first few hours of life and therapy with ampicillin sodium and gentamicin sulfate was begun for treatment of possible sepsis. The antibiotic therapy was discontinued after 48 hours in all patients on receipt of negative culture reports. A seizure disorder developed in case 5 at six

hours of age and therapy with phenobarbital was begun.

Gross hematuria was detected during the first 48 hours of life in all patients except case 2, in whom microscopic hematuria developed two days and gross hematuria four days after birth (Table 1). Proteinuria was present in all patients and cases 4 and 5 had oliguria for a mean period of five days. The blood pressure was recorded in three infants during the acute state of the disease and was normal in all.

Enlarged kidneys were first noted at the onset of hematuria in three infants and within three days in the other two infants. Three infants (cases 1 to 3) had unilaterally and two (cases 4 and 5) had bilaterally enlarged kidneys (Table 1). At the time of initial evaluation, the serum creatinine level was increased in all patients and the BUN level was elevated in three patients (Table 2). The highest ratios of BUN level-creatinine level were 28 to 1.8, 28 to 1.9, 12 to 1.5, 44 to 5.7, and 26 to 6.7 mg/dL in cases 1 to 5, respectively. The two infants with bilateral RVT (cases 4 and 5) had serum potassium concentrations of 6.5 and 6.6 mEq/L, respectively, during the acute stages of the illness and case 5 had persistent hyperkalemia (6.1 to 6.7 mEq/L) throughout his first year of life.

Results of initial urographic and renal isotopic studies (Table 2) correlated with physical findings; unilaterally enlarged kidneys were nonfunctioning or abnormal and bilaterally enlarged kidneys were both abnormal. Results of inferior vena cavagraphy in the two cases studied were not diagnostic of RVT.

Case 5 showed severe anemia due to abruptio placentae and was given a blood transfusion shortly after birth. The peripheral blood smear from three infants (cases 2, 4, and 5) showed occasional fragmented RBCs and burr cells, and the platelet count was decreased in these same infants (< 100,000/cu mm). However, the levels of plasma fibrinogen and fibrin split products were normal.

Case 4 received therapy with heparin sodium during the period of oliguria (seven days). He initially received 100 units/kg of heparin sodium as a single dose followed by 25 units/kg/hr. The dosage of heparin sodium was adjusted every eight hours to maintain the partial thromboplastin time (PTT) between 2½ to three times normal. In spite of careful calculations, the PTT was usually either below or above the desired range.

FOLLOW-UP STUDIES

Case 1.—At 38 months of age, this patient had normal renal function (Table 3). The results of radiographic studies, however, showed a small, shrunken right kidney and an enlarged left kidney (Fig 1). There was some evidence of delayed psychomotor development that was considered secondary to environmental deprivation.

Case 2.—This patient became slightly hypertensive by 4 months of age. At 17 months of age, an intravenous (IV) urogram showed a small shrunken left kidney (Fig 2) and a hypertrophied right kidney. Chest roentgenogram and ECG were normal. Results of selective renal vein renin assay showed elevated renin levels; the right side was 39.5 ng/mL/hr and the left side 30.3 ng/mL/hr (normal, 1.5 ng/mL/hr). By aortography, the left renal artery was detectable but smaller than the right renal artery (Fig 3). This patient received no antihypertensive therapy and his blood pressure has been normal for the past 12 months. Renal function at 32 months of age was normal (Table 3). His height was at the third percentile.

Case 3.—This patient has been lost to follow-up.

Case 4.—At 24 months of age, this patient had impaired renal function (Table 3) and was receiving sodium bicarbonate.

The latest anatomical studies were performed at 11 months of age. On IV urogram, the right kidney did not appear. Results of radioisotopic study showed reduced perfusion and concentration in both sides, with the right side more impaired than the left (Table 4).

CASE 5.—At 11 months of age, case 5 had appropriate height and weight, but renal function was impaired (Table 3). His therapy included sodium bicarbonate because of acidosis. An inferior vena cavagram performed at 2½ months of age was normal. There was bilateral "washout" of contrast at the level of the renal veins (Table 4). Intravenous urography at 2½ months of age showed no excretion of contrast medium from either kidney for up to three hours, but the renal scan was normal. When last seen at age 25 months, renal function was abnormal but growth and development were normal (Table 3). Neonatal seizure activity required continued therapy with phenobarbital and no seizures have occurred subsequently.

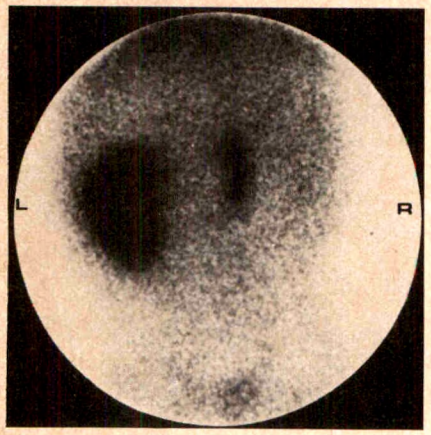

Fig 1.—Follow-up renal scan, case 1 at 16 months of age. Minimal concentration of radionuclide in small right kidney. Left kidney is enlarged and has normal concentration of isotope (Tc 99m diethylenetriamine penta-acetic acid).

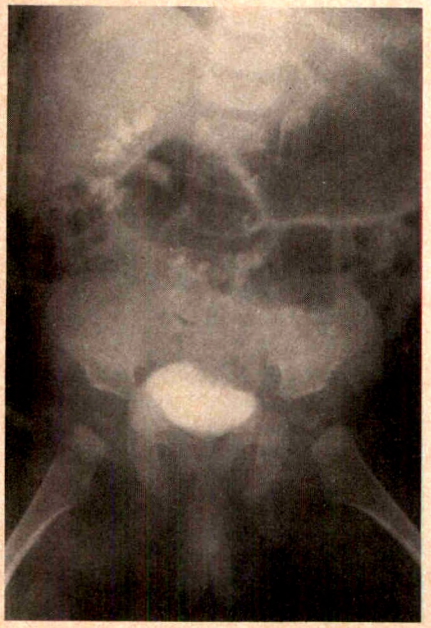
Fig 2.—Intravenous urogram, case 2 at 7 months of age. Right kidney is larger than normal but left kidney is small and has decreased concentrations of contrast medium.



COMMENT

The natural history of RVT in infants has received considerably less attention than have the early diagnostic and therapeutic aspects of this disease. In the course of this study of five infants with RVT, a variety of physiological and roentgenographic abnormalities appeared in four infants after an observation period of from 24 to 32 months. The residual defects from neonatal RVT resembled those seen in other congenital and acquired lesions, which emphasizes the importance of careful evaluation and follow-up of infants with suspected neonatal RVT.

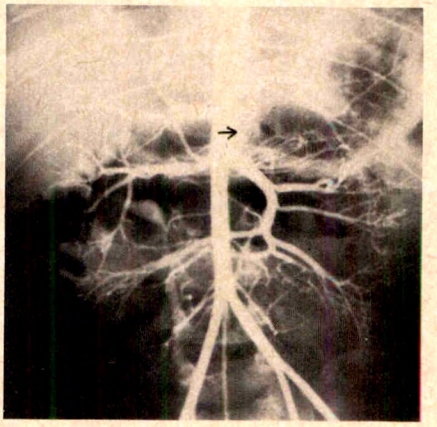


Fig 3.—Arteriogram, case 2 at 17 months of age. Left renal artery (arrow) is very small, but right renal artery is normal.

Only two infants, both having had bilateral RVT, had slight elevations of serum creatinine level at follow-up (creatinine levels, 0.8 and 1.2 mg/dL, respectively). These infants required bicarbonate replacement; one had polyuria as well as hyperkalemia during his first year of life (case 5). Although glomerular filtration was reduced in these two infants (as reflected by slightly elevated serum creatinine levels), interstitial and tubular damage seemed to be more important during the period of observation.

Hypertension is a feared consequence of neonatal RVT, yet the incidence of this complication was only 6/50 cases in one review.[5] The only patient in our series with hypertension (case 2) was not treated and the hypertension has disappeared. A small renal artery and a shrunken kidney with hypertrophy of the contralateral kidney were detected in case 2 and have been mentioned by other workers.[9] In the absence of prior clinical information, these radiographic abnormalities might otherwise suggest the presence of a congenitally dysplastic or "hypoplastic" single kidney.

Table 4.—Follow-up Anatomical Studies

Case	Intravenous Urogram (Age at Time of Study)	Renal Scan (Age at Time of Study)
1	R, small-minimal visualization L, large-normal visualization duplex system (28 mo)	R, reduced perfusion and concentration L, normal perfusion and concentration (28 mo)
2	R, large-normal visualization L, small-minimal visualization (7 mo)	R, normal perfusion and concentration L, reduced perfusion and concentration (7 mo)
3	R, large-normal visualization L, small-minimal visualization (3 mo)	
4	R, no visualization L, minimal visualization (11 mo)	R, reduced perfusion and concentration L, reduced perfusion and concentration (11 mo)
5	R, no visualization L, no visualization (2½ mo)	R, normal perfusion and concentration L, normal perfusion and concentration (2½ mo)

Consequently, we believe that detection of a small renal artery is not sufficient evidence of a congenital rather than acquired small kidney.

Radiographic IV urography, inferior vena cavagraphy, aortography, renal scan,[9] and ultrasonography are helpful in supporting the clinical diagnosis, but none of these procedures are definitive. The renal scan correlated well with the ultimate outcome in our series, and in view of its small amount of radiation exposure, it may be a particularly useful test for RVT. Evidence of RVT in the arterial phase of aortography includes stretching or bowing of the interlobular vessels and delayed transit time of the contrast medium.[10,11] In the urographic phase, whether the injection is made via umbilical catheter or through a peripheral vein, the kidneys are not demonstrable on the affected side in most patients with RVT.[4,11] We performed vena cavagraphy on only two cases and in each it was normal. The stream of unopacified blood from the renal vein may produce a radiolucent image (washout) in the inferior vena cava at the L1 to L2 level during vena cavagraphy. However, absence of washout is not specific for RVT, as it can also occur in some healthy persons[12] or in persons with any renal disorder in which there is a reduction in renal blood flow. Furthermore, failure to detect thrombosis of the inferior vena cava cannot eliminate the diagnosis of RVT due to the variability in the site of thrombosis.

Anemia, fragmented RBCs and burr cells, as well as thrombocytopenia, decreased serum fibrinogen, and increased fibrin degradation products have been reported in patients with RVT. These findings raise the probability of consumptive coagulopathy accompanied by RVT,[13] but the condition of the only patient in our series who received heparin has progressed to renal failure.

The emphasis of the management of the neonate with RVT should be placed on the maintenance of normal fluid and electrolyte balance.[4] Some patients may require peritoneal dialysis although this was not necessary in our series. Unilateral thrombectomy or nephrectomy during the acute stages is generally not advocated.[2,5,9] Since Stark[2] first noted survival of infants with RVT not subjected to nephrectomy, several reports have confirmed the safety of this nonsurgical approach.[9,14] Nephrectomy had previously been advocated to prevent (1) infection, now an infrequent complication, (2) hypertension, a serious problem usually after healing and renal atrophy occurs, and (3) extension of thrombosis, an apparently rare complication in neonatal RVT.[9] Furthermore, many instances of return of function in the damaged kidney are now documented. Subsequent nephrectomy for persistent hypertension may be required, however.[4,9] Thrombectomy for bilateral involvement has been successfully performed at some centers,[15] but the role of this procedure in RVT is presently unclear.

Christopher F. O'Connor and Brendan M. Fox referred their patients. Susan Maguda gave secretarial assistance.

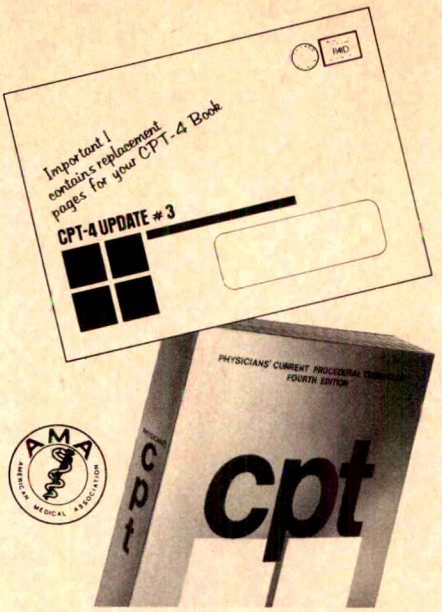
Announcing... UPDATE No.3 for CPT-4!



That's what keeps CPT-4 the most current medical reporting system you can use!

The 4th Edition of *Physicians'* CURRENT PROCEDURAL TERMINOLOGY is the only coding system that provides new and revised terminology on a regular, automatic basis. This latest update, Summer 1979, marks the third update since CPT-4 was published in 1977.

The updates are on self-adhering pages that are affixed to the pages they replace in CPT-4. To activate the automatic update mechanism, you simply return the postage-free card in the book.

CPT-4 is a uniform coding system to accurately designate medical, diagnostic, and surgical services in terms of a uniform language among physicians, patients, and third parties.

Shouldn't you be using the most current coding system available?

Order two—one for yourself, one for your medical records clerk.

Order Dept., OP-41

SYNEMOL®
(FLUOCINOLONE ACETONIDE)
CREAM 0.025%

Description SYNEMOL (fluocinolone acetonide) has the chemical name 6α, 9α-difluoro-16α-hydroxyprednisolone-16, 17-acetonide.

The cream contains fluocinolone acetonide 0.25 mg./g. in a water-washable aqueous emollient base of stearyl alcohol, cetyl alcohol, mineral oil, propylene glycol, sorbitan monostearate, polysorbate 60, purified water and citric acid.

Indications Inflammatory manifestations of corticosteroid-responsive dermatoses.

Contraindications Topical steroids are contraindicated in those patients with a history of hypersensitivity to any of the components of the preparation.

Precautions If irritation develops, discontinue the product and institute appropriate therapy.

In the presence of an infection institute the use of an appropriate antifungal or antibacterial agent. If a favorable response does not occur promptly, discontinue the corticosteroid until the infection has been adequately controlled.

If extensive areas are treated or if occlusive technique is used, there will be increased systemic absorption of the corticosteroid and suitable precautions should be taken, particularly in children and infants.

The safety of topical steroids in pregnant women has not absolutely been established. In laboratory animals, increases in incidences of fetal abnormalities have been associated with exposure of gestating females to topical corticosteroids, in some cases at rather low dosage levels. Therefore, drugs of this class should not be used extensively on pregnant patients, in large amounts or for prolonged periods of time.

SYNEMOL® (fluocinolone acetonide) cream is not for ophthalmic use.

Adverse Reactions Local adverse reactions reported with topical corticosteroids: burning, itching, irritation, dryness, folliculitis, hypertrichosis, acneform eruptions, hypopigmentation, perioral dermatitis, allergic contact dermatitis, maceration of the skin, secondary infection, skin atrophy, striae, miliaria.

How Supplied
SYNEMOL® (fluocinolone acetonide) Cream 0.025%—15, 30 and 60 g. tubes.

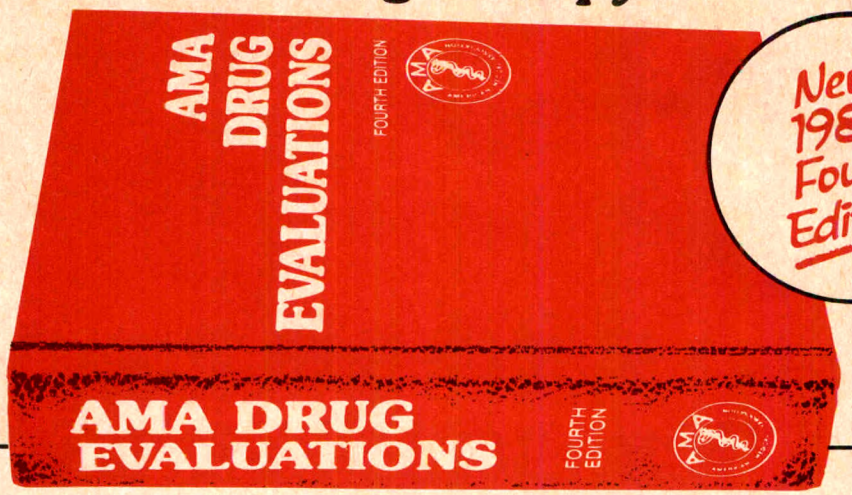
Just off the press!

The most useful and definitive book on drug therapy!



New 1980 Fourth Edition!

Over 1,300 drugs evaluated including 57 new drug listings!

New Fourth Edition!

Important NEW Features!

- 87 chapters, completely reorganized and updated.
- New chapters on Antiviral Agents, Immunomodulators, Parenteral and Enteral Nutrition, and Agents Used to Treat Infertility.
- Expanded discussion on dosages for special age groups.
- Selected references at end of each chapter.
- Expanded information on investigational drugs
- Comprehensive index by drug name, indications, adverse reactions.

Completely reorganized, updated and expanded, *AMA Drug Evaluations, Fourth Edition*, is the most inclusive, comprehensive, and objective drug compendium ever assembled, covering virtually every significant drug prescribed in the U.S. today.

An indispensable, clinically-oriented guide for prescribing, dispensing, or administering drugs

Organized by therapeutic category, each chapter begins with an introductory overview, followed by detailed evaluations for individual drugs. *AMA DE/4* gives information on dosage, actions and uses, contraindications, and includes structural formulas for most single-entity drugs—plus a listing for hundreds of additional mixtures and proprietary preparations.

THE Authoritative Guide—prepared by the AMA and ASCPT

Whether you need detailed therapeutic information for a class of drugs, the proper dosage for a drug or a manufacturer's address, you can rely on *AMA DE/4*. You can be totally confident the information is accurate and clinically pertinent because it has been compiled by members of the American Medical Association's Department of Drugs working closely with the American Society for Clinical Pharmacology and Therapeutics and a consulting panel of more than 300 distinguished physicians and other health care professionals.

Order your copy of AMA DE/4 today!

It is the most inclusive, objective, and clinically-oriented reference on drug therapy you can use. The price is only $48.00. To order, complete the form below and return with your payment today!

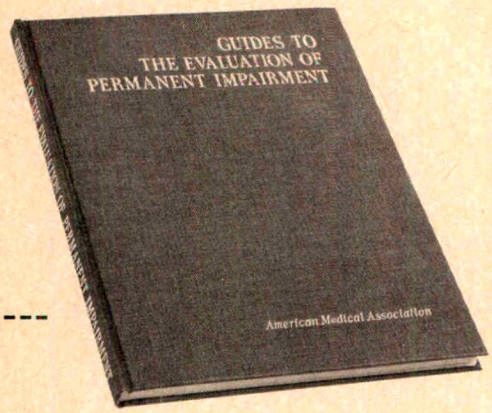
Do you have GUIDES TO THE EVALUATION OF PERMANENT IMPAIRMENT on your reference shelf?

If not, now is the time to fill the void!

Guides to the Evaluation of Permanent Impairment contains a series of practical guides for the rating of physical and mental impairment of all systems of the body. Published by the American Medical Association, this important volume will assist you in discharging your responsibility to patients who are seeking benefits from the various agencies and programs serving the disabled.

Each guide provides recommended percentage values related to the criteria given. Numerical values offer a practical means of expressing and calculating the extent of permanent impairment and encourage accurate, equitable, and uniform evaluation. Methods of impairment calculation are uniform, are explained in detail with examples, and need a minimum of computation. A Combined Values Chart is provided for easily assessing any combination of impairments.



A partial table of contents includes:

- The Central Nervous System
- The Peripheral Spinal Nerves
- The Endocrine System
- The Digestive System
- The Extremities and Back
- Mental Illness
- The Visual System
- The Cardiovascular System

Campomelic Dysplasia

Further Elucidation of a Distinct Entity

Bryan D. Hall, MD, Jürgen W. Spranger, MD

• Campomelic dysplasia is a distinct entity that should not be confused with other conditions associated with congenital bowing of the long bones. Evidence suggests that some affected males have female external genitalia, and vagina, uterus, and fallopian tubes. Examination of a newly reported sibling pair has increased support for autosomal recessive inheritance in campomelic dysplasia.

(*Am J Dis Child* 134:285-289, 1980)

The term "campomelic syndrome" or "campomelic dysplasia" (the latter is the preferred term[1]) was originally coined to describe a distinct entity.[2] Later, it was also applied to other disorders that share the feature of campomelia; ie, bowed extremities, such as short-limb craniosynostotic and normocephalic campomelic varieties.[3] This not only was confusing, but also implied a pathogenetic relationship between different bowing conditions. It also served to divert attention from the fact that bowing of the extremities is a nonspecific sign of etiologically different conditions. In our opinion, the term campomelic dysplasia should be reserved strictly for a single distinct entity, as reported originally by Spranger et al[2] and Maroteaux et al.[4] Attempts to bring order to the vast array of conditions with congenitally bent or bowed legs should not create new confusion by using the same or similar names for different disorders. We reviewed the features of classic campomelic dysplasia to establish firm criteria with which to separate it from other disorders that share the sign of congenitally bowed extremities.

From the Department of Pediatrics, University of California, San Francisco (Dr Hall), and the Kinderklinik, University of Mainz, Germany (Dr Spranger).

Reprint requests to M648, Department of Pediatrics, University of California, San Francisco, CA 94143 (Dr Hall).

SUBJECTS AND METHODS

Six new cases from the Skeletal Dysplasia Registry of the Children's Hospital of the University of Mainz, Germany, and 37 case reports from the literature[3-19] form the basis of this report. Since only a few case reports contained information on every aspect of the disorder, the incidence figures were frequently developed on fewer than 43 cases. Some clinical and roentgenographic features, such as long philtrum, small mouth, hallux deviation, brachydactyly, and nonmineralization of thoracic pedicles, were often not commented on by authors or in some of our patients' charts; in these cases, the listing of such features in the tables was based solely on our observations of a patient's photographs and roentgenograms. All six subjects of the present series died between 2 and 34 days of age, and 27 of 31 cases from the literature also died early. For this reason, no specific data will be given on mental retardation, although one long-term survivor is severely retarded.[4]

RESULTS

Gestational data, clinical features, roentgenographic abnormalities, and major pathological findings of the 43 cases are listed in Tables 1 through 3, and will be discussed later. Gestational data that were normal or not pertinent were omitted from the tables. Notably, we found no increased maternal exposure to drugs or gestational difficulties except for a 36% (nine/25) incidence of polyhydramnios. A genetic analysis of the families of our six patients showed that case 5 had a similarly affected sibling. This sibling's sex is unknown and the child is not tabulated in our series because we could not verify the medical information. The mean maternal (23.6 years) and paternal (26.8 years) ages at the time of the birth of their affected children were normal, as were those of the parents reported in the literature.

A total of 17 patients, including our cases 1 and 5, had karyotypes determined. Eight of 17 (47%) had 46,XY karyotypes, despite being phenotypic females. The breakdown of these results is in Table 4. The results of numerous laboratory studies are not listed. They included the determination of levels of serum calcium, phosphorus, alkaline phosphatase, urine amino acids, and glycosaminoglycans, all of which were normal.

§Means ears are either abnormal in size, shape, or position.

COMMENT

The clinical picture that has emerged from this study (Table 1) is that of a low-normal weight, term newborn with a disproportionately large, dolichocephalic head (Figure, F) and disproportionate shortness, particularly of the lower extremities. The facies (Figure, E) is clearly abnormal with micrognathia, small mouth, cleft palate, long philtrum, flat nasal bridge, hypertelorism, "slit-eyes" (narrow palpebral fissures), and abnormal ears. The bell-shaped chest (Figure, A) is small, giving the abdomen the appearance of being large and protuberant. The upper extremities may be slightly short but are rarely bowed. The hands show mild brachydactyly and various degrees of clinodactyly (Figure, C and D). The lower extremities show symmetrical anterior bowing with pretibial dimples and talipes equinovarus (Figure, A, B, K, and L). Hypotonia, medial deviation of the hallux (Figure, M), and dislocations at the hip, elbows, or fingers are frequently present. Difficult respirations, apneic episodes, cyanosis, and feeding difficulties persist until death, which occurs within the first month of life in the majority of cases. Major abnormalities appearing on roentgenograms (Table 2) in addition to the characteristic lower-extremity bowing include the following: (1) absent or hypoplastic scapulae (Figure, A and J), (2) nonmineralization of the thoracic pedicles (Figure, H), and (3) narrow, vertical ilial bones (Figure, A and L). Other particularly useful diagnostic features are the hypoplastic cervical vertebrae (Figure, G), widely spaced ischial bones (Figure, A and L), and absence of the distal femoral and proximal tibial epiphyses (Figure, A). It should be emphasized that the femoral bones are not broad and their shortening is due primarily to the bowing, whereas the tibial bones are often broad and short (Figure, K) in addition to being bowed.

Some anatomic features (Table 3) are of diagnostic importance, particularly in patients who die without adequate clinical or roentgenographic documentation. Findings such as absent or hypoplastic olfactory bulbs (tracts) and hypoplastic trachea or cartilaginous rings with or without heart defects and hydronephrosis would be highly suggestive of campomelic dysplasia in a child with congenital symmetrically bowed lower extremities. The surprisingly high frequency of hydronephrosis (38%) and congenital heart defects (21%) has not been previously emphasized in campomelic dysplasia.

The differential diagnosis of campomelic dysplasia must initially include all bone dysplasias with congenital bowing[5,6] and early death.[21-23] Among the well-established disorders, the differentiation is not difficult using the findings in Tables 1 through 3. However, we have had some difficulty with diastrophic dwarfism[24] and Larsen's syndrome[25] in the neonatal period. These two disorders share with campomelic dysplasia the clinical features of cervical vertebral anomalies, cleft palate, joint dislocations, talipes equinovarus, clinodactyly, bowed extremities, and laryngotracheal abnormalities.[26,27] The campomelic syndrome also shares abnormal ears, micrognathia, medial deviation of the hallux, and brachydactyly with dias-

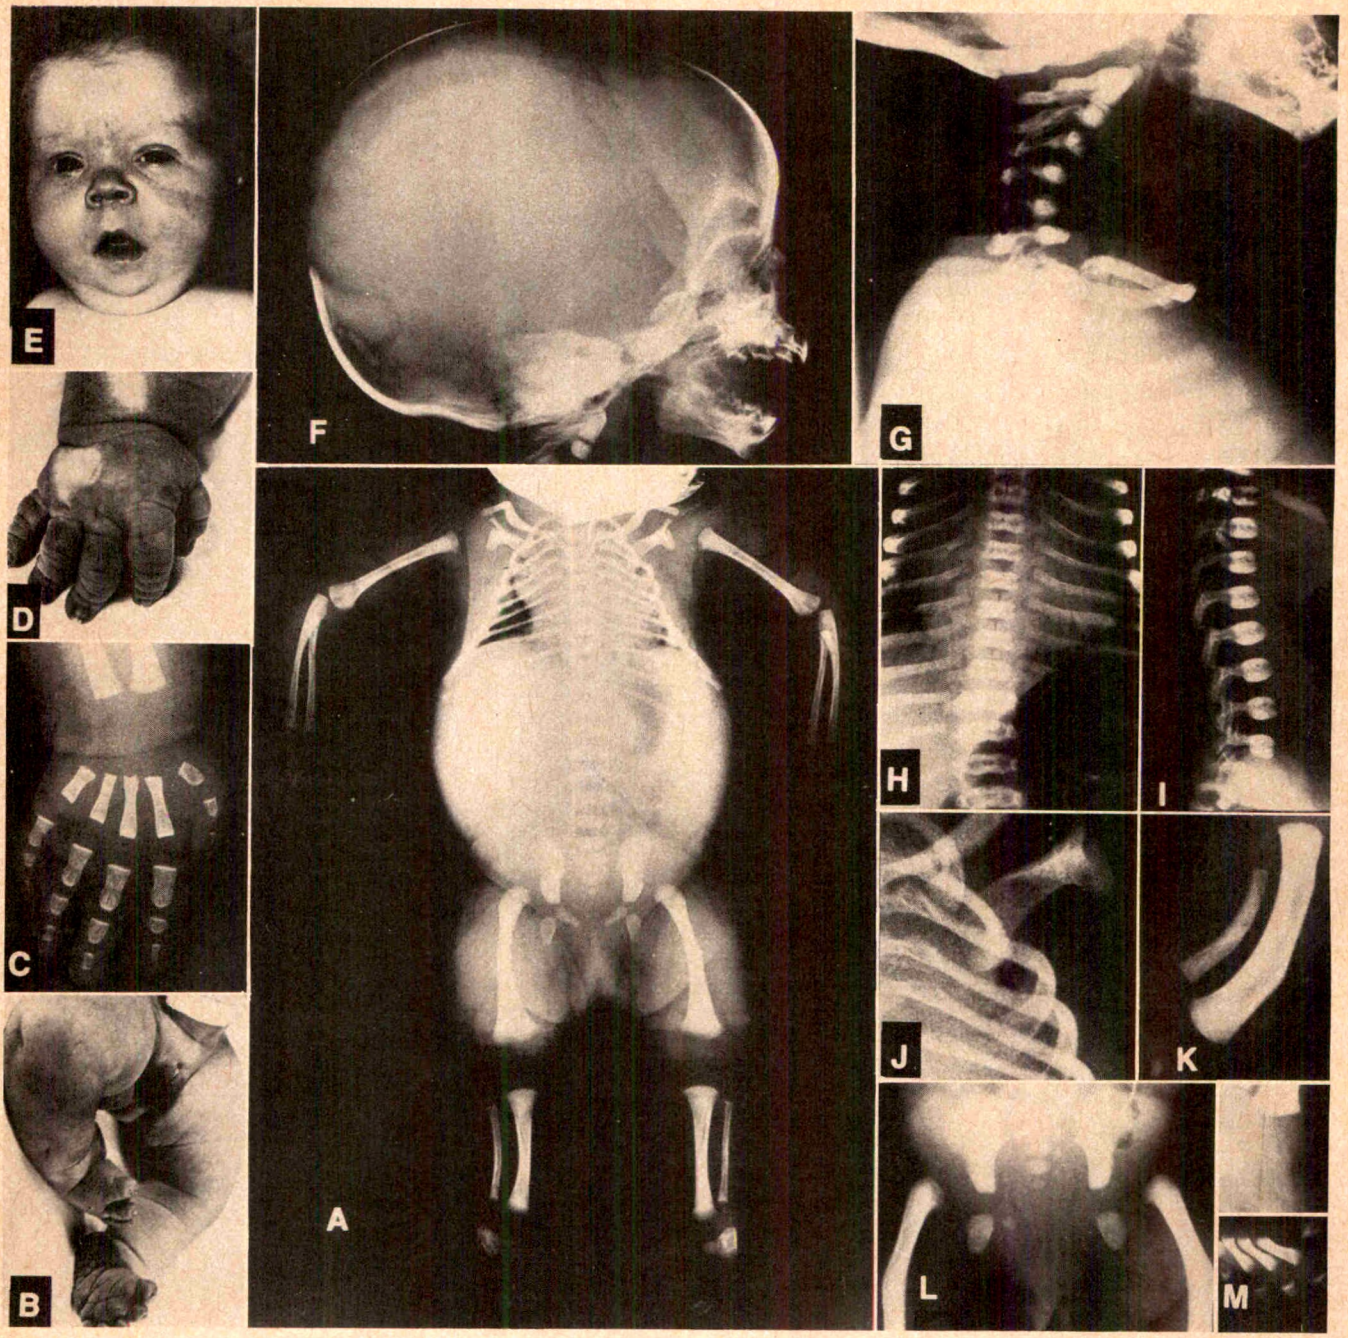
*Excluded from clinical tables because no comment was made in the report on limb bowing.



(A) Full-body posteroanterior view. (B) Tibial bowing with pretibial dimples and equinovarus deformity. (C, D) Brachydactyly, clinodactyly, and widened distal phalangeal tips. (E) Facies showing flat nasal bridge, long philtrum, small mouth, and micrognathia. (F) Macrocephaly with large anterior fontanel. (G) Hypoplastic cervical vertebrae. (H) Nonmineralized thoracic pedicles. (I) Normal lower thoracic and lumbar spine. (J) Hypoplastic scapula. (K) Short, broad, and anteriorly bowed tibia. (L) Vertically narrow ilial bones with widely spaced ischial bones and bowed femora. (M) Equinovarus deformity with hallux deviation.

trophic dwarfism, and flat nasal bridge and hypertelorism with Larsen's syndrome.[25] Comparison of the scapulae, thoracic pedicles, and ilial bones between these entities should allow a secure diagnostic separation. Of course, the multitude of unknown types of bone disorders with congenital bowing will remain a problem; however, using the features tabulated here, it should be possible to tell whether or not a patient has campomelic dysplasia.

The association of a skeletal dysplasia in a karyotypic 46,XY male who has female external genitalia and vagina, uterus, and Fallopian tubes is difficult to explain. Prior to seeing case 5, we were reluctant to accept this association. Our case 5 had classic features of campomelic dysplasia, female genitalia, and a male karyotype. Unfortunately, no autopsy was performed, so the appearance of the gonads is unknown. Most of the reports[16,18-20] of gonadal studies did not adequately document the clinical and roentgenographic aspects, leaving some doubt regarding the diagnosis of campomelic dysplasia; however, Hovmöller and associates[17] reported two such instances that were well documented. The pathological findings were adequately investigated in three of the previously mentioned reports, and all found either poorly differentiated ovarian tissue in the ovarian fossa[16,17] or gonadal tissue with an embryonal testicular pattern.[20] All of these patients also had normal-appearing external female genitalia, vagina, uterus, and Fallopian tubes. This sex-reversal phenomenon may explain the "female" preponderance of 29:8 among our tabulated cases. A comparison (Table 4) of the phenotypic sex and karyotypic sex in all patients who were karyotyped,[4-7,11,16-20] including our cases 1 and 5, show a more equal sex ratio of 20:14, female to male.

The inheritance pattern of campomelic dysplasia is not yet definitely established. Present evidence suggests an autosomal recessive mode of inheritance based on similarly affected mixed-sex siblings of normal parents as reported by Thurmon et al,[8] Shafai and Schwartz,[9] and ourselves (case 5), plus a report of consanguinity by Cremin and associates.[28] Our review of the published data show a total of 60 pregnancies, 15 abortions, 25 probands, 17 normal siblings (seven male, six female, four sex unknown) and three similarly affected siblings. Case 1 from Thurmon et al (Table 4, no. 9)[8] is not included as a similarly affected sibling because the patient's condition was very poorly documented and he was also a half-sibling. Once the probands and abortions are excluded, a 15% incidence (three/20) of similarly affected siblings is obtained that is closest to an expected autosomal recessive gene occurrence of 25%.

Campomelic dysplasia is a distinct syndrome, with all of its major clinical and roentgenographic features occurring with a greater than 50% frequency. Three of its regular roentgenographic features, namely hypoplastic scapulae, nonmineralized thoracic pedicles, and vertically narrow ilial bones, are rare findings in themselves and unique in combination. With adequate documentation, campomelic dysplasia should not be confused with other disorders involving congenital bowing of the lower extremities.

This investigation was supported by a grant from the Stiftung Volkswagenwerk, and by an Alexander von Humboldt Fellowship, Bundesrepublik Deutschland, to Dr Hall.

Acute Isoniazid Poisoning in Childhood

Jeffrie Miller, MD; Anita Robinson, MD; Alan K. Percy, MD

• Acute isoniazid poisoning is uncommon in children. Only 27 cases, to our knowledge, have been reported in the literature. Often, the first observation is of uncontrollable convulsions. The metabolic alterations are often striking and the treamtent has mainly been supportive, with the judicious use of pyridoxine hydrochloride in those cases in which a history of ingestion of isoniazid is obtained. The response to the administration of pyridoxine has been difficult to evaluate.

(*Am J Dis Child* 134:290-292, 1980)

Although ineffective therapy of prolonged, generalized seizures (status epilepticus) is commonly associated with inadequate doses of anticonvulsants, failure to recognize other causes of persistent, generalized convulsions may lead to otherwise unnecessary morbidity and mortality. Since the introduction of isoniazid in 1952, periodic reports of intentional or accidental intoxications complicated by generalized convulsions have appeared.[1-8] Such poisoning may present a dangerous, life-threatening situation in which medical management must be pursued aggressively. Awareness of such poisonings is particularly relevant to children, in whom isoniazid is a commonly used antituberculous agent. Four cases of isoniazid poisoning have been encountered at Martin Luther King, Jr, General Hospital, Los Angeles.

REPORT OF CASES

CASE 1.—A 1½-year-old boy was brought to the Pediatric Acute Care Clinic in the midst of a general convulsion. According to his mother, the child had been in good health one hour prior to admission. Shortly after the patient's arrival, a 2½-year-old sibling who was convulsing and a 4-year-old sibling who was lethargic were both brought into the clinic by their father. An empty bottle of 300-mg isoniazid tablets found in the home was brought with the two siblings, one of whom was currently receiving treatment with prophylactics for tuberculosis. Results of physical examination of the 1½-year-old child at the time of admission were unremarkable except for generalized seizure activity. He was afebrile and had no localizing neurological signs. Before the history of ingestion was elicited, the patient was given dextrose (1 g/kg) and a total of 10 mg of diazepam (Valium) intravenously without any noticeable decrease in seizure activity. The additional administration of phenytoin (Dilantin), 150 mg intravenously, also was without avail. Continued seizure activity was accompanied by respiratory embarrassment that necessitated endotracheal intubation and intermittent ventilation. The convulsions ceased after the administration of 6 mL of paraldehyde rectally. The entire duration of seizure activity was 2½ hours. After obtaining a history of presumptive isoniazid ingestion, the patient was also given 150 mg of pyridoxine hydrochloride intravenously. Abnormal laboratory findings at the time of admission included the following values: WBCs, 21,000/cu mm, with a lymphocytosis; ketonuria; serum bicarbonate, 13 mEq/L; and, glucose, 355 mg/dL. An initial arterial blood sample showed a severe metabolic acidosis, with a pH of 7.13, a base excess of −15 mEq/L and a P_{CO_2} of 48 vol%. A chest roentgenogram showed a right upper lobe infiltrate. Serum isoniazid level was 103 μg/mL, almost ten times the maximum therapeutic level. Analyses of isoniazid levels were performed by the University of Southern California-Los Angeles County Toxicology Laboratory, using a modification of Maher's method.[9]

The morning after admission, no further seizure activity was noted. The remaining hospital course was complicated by postextubation laryngeal edema that required a tracheostomy. The patient's condition improved thereafter and he was discharged after a 20-day hospitalization period. When seen in the follow-up clinic one week after discharge, the patient was in good health without evidence of neurologic deficit.

CASE 2.—The 2½-year-old sibling of case 1 was also noted to have generalized seizure activity on admission. Control was achieved by the administration of 10 mg of diazepam and 100 mg of pyridoxine hydrochloride intravenously. The history indicated that this sibling was receiving isoniazid for treatment of tuberculosis.

Physical examination at the time of admission showed an actively convulsing boy without lateralizing neurological signs. Vital signs were within normal limits. Pertinent laboratory values were as follows: WBCs, 21,000/cu mm; serum bicarbonate, 12 mEq/L; and, serum glucose, 255 mg/dL. The serum isoniazid level was 35 μg/mL.

The patient remained comatose throughout the night, unresponsive to painful stim-

uli, and with sluggishly reactive pupils. By the next morning, the patient was fully alert, with no further seizure activity. He was discharged home after four days and is being followed up at the Public Health Clinic for tuberculosis.

CASE 3.—That same night, the 4-year-old sibling of case 1 was noted to be lethargic, and isoniazid poisoning was suspected, although no seizure activity was observed. His medical history indicated that he was also taking isoniazid for a positive PPD and roentgenographic evidence of perihilar adenopathy. Physical examination showed a 20-kg boy who was mildly lethargic without lateralizing neurological signs. Complete blood cell counts and blood chemistry levels were normal. Chest roentgenogram showed perihilar adenopathy. On the morning after admission, the patient was alert and active. A blood sample was sent for an isoniazid assay. The laboratory was unable to provide this information. The patient was discharged and on follow-up in the Public Health Clinic was in satisfactory health.

CASE 4.—A 16-year-old girl was brought to the pediatric emergency room in the midst of a general convulsion. A partially empty bottle of isoniazid tablets was found near the patient, and a presumptive diagnosis of isoniazid overdose was made. The administration of 10 mg of diazepam intravenously temporarily interrupted the seizures; however, depressed respiratory function necessitated intubation. Fifteen minutes later, seizure activity recurred and the patient was subsequently given 15 mL of paraldehyde rectally and 300 mg of pyridoxine hydrochloride intravenously, with immediate cessation of all seizure activity. The patient was comatose, with no response to any external stimuli, her pupils were pinpoint, and her deep tendon reflexes were severely decreased. Laboratory findings included a serum pH of 6.84; serum glucose level of 324 mg/dL; and a WBC count of 16,800/cu mm. The severe metabolic acidosis was treated with a total of 180 mEq of sodium bicarbonate to a pH of 7.34.

Approximately one hour later, the patient's blood pressure suddenly fell to nonpalpable levels. A dopamine hydrochloride infusion was begun and her blood pressure rose to 50/20 mm Hg. Six hours after admission, the patient had a cardiac arrest and was resuscitated successfully. Shortly thereafter, a second cardiac arrest ensued, resuscitation efforts were unsuccessful, and the patient died after a seven-hour hospitalization. A serum isoniazid determination obtained on admission was 127 μg/mL. Permission for autopsy was refused.

COMMENT

Since the introduction of isoniazid in 1952, 27 cases in children of intentional or accidental isoniazid intoxication have, to our knowledge, appeared in the English-language literature.[1-8] Three of the 27 children died. Two of these deaths occurred among children in an Alaskan Eskimo village who were being given prophylactic isoniazid. There was no detailed description of their clinical course. The other death, reported by Kelso et al[3] in 1965, was that of a 15-year-old girl in whom, after ingestion of 5 g of isoniazid, intractable seizures, oliguria, hypotension, hyperpyrexia, and deep coma developed. She died approximately 70 hours after ingestion.

Among the surviving patients, ages ranged from 15 months to 16 years. Clinical signs and symptoms included nausea, vomiting, hypotension, leukocytosis, hyperpyrexia, respiratory distress, intractable seizures, and coma.

The amount of isoniazid ingested varied from 0.9 to 20 g and serum isoniazid levels were between 8 and 35 μg/mL in the five cases where levels were obtained (the therapeutic range is considered to be 0.5 to 12 μg/mL). Generalized seizures have been described previously in patients receiving as little as 35 to 40 mg/kg of isoniazid intramuscularly,[10] and 200 mg/kg is thought to be an obligatory convulsant dose in man.

The rate of elimination of isoniazid is a major determining factor in the manifestation of toxicity. The primary route of isoniazid inactivation is by acetylation. Persons may be identified as either slow, intermediate, or fast acetylators. Approximately 60% of all whites and blacks are slow acetylators, as opposed to only 10% of all orientals and Eskimos.[11] Consequently, both a higher incidence and a more severe form of toxicity might be expected in these former individuals.

The metabolic alterations produced by isoniazid intoxication are substantial and have included severe metabolic acidosis, ketonuria, hyperglycemia, mild hyperkalemia, and increased urinary excretion of pyridoxine.[5] These observed changes are due to a complex of pharmacological alterations involving pyridoxine metabolism. First, isoniazid lowers the effective tissue and serum level of pyridoxine through the formation of isoniazid-pyridoxine hydrazones that are rapidly excreted via the kidney.[12] Second, these same hydrazones competitively inhibit pyridoxine kinase, the activating enzyme that converts pyridoxine to the physiologically active pyridoxal phosphate.[12,13] Third, isoniazid inactivates pyridoxal phosphate-containing enzymes through the same coupling mechanism. Specific enzyme functions involved include amino acid transaminases and decarboxylases. In addition, a reduction in the pyridoxine level has an adverse effect on both the formation and catabolism of the inhibitory neurotransmitter, γ-aminobutyric acid (GABA).[12,13] The reduction in GABA turnover may explain, at least in part, the intractable seizures produced by isoniazid intoxication.

There is laboratory and clinical evidence that the antagonistic action of isoniazid on pyridoxine does not completely explain the metabolic alterations observed. This implies, perhaps, a wider spectrum of metabolic disturbance than that of the pyridoxal-dependent pathways alone.

In laboratory studies, administration of pyridoxine failed to protect animals from isoniazid-induced convulsions, whereas 50% of all animals given 200 mg/kg of isoniazid were protected by the administration of niacinamide (400 mg/kg).[12] Furthermore, there are clinical accounts of patients who have taken large doses of isoniazid and pyridoxine in combination, but who nevertheless manifested severe convulsions.[4] At the molecular level, isoniazid interferes with nicotinamide adenine dinucleotide (NAD)-catalyzed reactions.[4,14] Nicotinamide adenine dinucleotide is recognized as an essential component of the energy-producing reactions of glycolysis and the tricarboxylic acid cycle. The introduction of isoniazid into the NAD molecule forms an inactive analogue of NAD that seriously disrupts intermediary metabolism.[14] Recently, niacinamide was noted to be as effective as pyridoxine in reversing isoniazid-induced hyperkinesis.[15] In light of these observations, there may

be justification on both clinical and biochemical grounds for the use of niacinamide in the treatment of isoniazid poisoning.

In the reported pediatric cases, pyridoxine was the most commonly used therapeutic agent. There were no case reports of therapy with niacinamide. The dosage of pyridoxine hydrochloride varied widely from a low of 20 mg to a high of 1,500 mg per 1,000 mg of isoniazid ingested. The dosage schedule varied from a single injection to four doses given over a period of 48 hours.

The concurrent use of anticonvulsants such as diazepam, phenobarbital, paraldehyde, phenytoin makes the evaluation of therapy with pyridoxine difficult. Phenytoin may even be toxic to those patients with a high serum isoniazid level.[16] Isoniazid is a potent inhibitor of phenytoin metabolism in man. Its mode of action seems to be as a noncompetitive inhibitor of the parahydroxylation of phenytoin, a major step in elimination of phenytoin from the body. The principal manifestations of phenytoin toxicity are lethargy, nystagmus, and ataxia. These factors are difficult to recognize in the comatose patient and may further complicate the clinical picture of isoniazid poisoning. Furthermore, clinical studies have shown that those patients phenotypically identified as slow inactivators of isoniazid are at an increased risk for phenytoin intoxication.[16]

The key issues for the clinician are the timely recognition of the offending agent and the successful management of the seizures, the metabolic abnormalities, and any resultant complications. Therapy with phenytoin should be avoided when a history of therapy or poisoning with isoniazid is known. The suggested interaction of isoniazid with NAD-catalyzed reactions warrants further clinical observations regarding the use of niacinamide along with pyridoxine in the treatment of isoniazid poisoning.

Lip Pits, Cleft Lip and/or Palate, and Congenital Heart Disease

Richard M. Pauli, MD, PhD, Judith G. Hall, MD

• **Three individuals in whom lip pits and cleft lip and/or cleft palate were found in association with congenital heart disease are described. These individuals did not have the characteristics of previously delineated syndromes in which lip pits occur, including Vanderwoude syndrome, popliteal pterygium syndrome, and orodigitofacial dysostosis. Literature review failed to show any previously reported cases in which pits were observed in association with congenital heart disease.**

(*Am J Dis Child* 134:293-295, 1980)

Bilateral, congenital, lower-lip pits is a rare anomaly most often seen in association with autosomal dominant inheritance of cleft lip and/or cleft palate (Vanderwoude syndrome).[1] Lip pits may also be seen as part of the popliteal pterygium syndrome,[2,3] and orodigitofacial dysostosis.[4] The following three cases are, to our knowledge, the first reported in which the distinctive and rare combination of lip pits and cleft lip and/or cleft palate has occurred with congenital heart disease.

From the Departments of Pediatrics (Dr Hall) and Medicine (Dr Hall) and the Center for Inherited Diseases (Drs Pauli and Hall), University of Washington School of Medicine, Seattle; and the Division of Medical Genetics (Drs Pauli and Hall), Children's Orthopedic Hospital and Medical Center, Seattle.

REPORT OF CASES

CASE 1.—This male infant was born on June 4, 1978, to a gravida 3, para 2, abortus 1 woman after a pregnancy complicated only by morning sickness in the tenth through 18th weeks. The father was 24 years old, the mother 25 years at the time of the birth. Drug exposure during gestation included vitamins and iron throughout pregnancy and incidental exposure to acetaminophen, aspirin, and calcium carbonate antacid, all in the second and third trimesters. Maternal weight gain was 9 kg; fetal activity was noted around the 16th week and was noted subjectively as less than in the mother's first pregnancy.

Following an easy vaginal delivery, complicated by late meconium staining, a 4,140-g, 51-cm dysmorphic male infant was born. He was transferred to Children's Orthopedic Hospital and Medical Center, Seattle, because of apparent congenital heart disease.

Abnormalities noted by physical examination included: complete bilateral clefts of the lip and palate; bilateral lip mounds (Fig 1); concave, slightly hypoplastic fingernails and toenails; broad halluces; a prominent crease between the first and second toes; and an inferior accessory nipple on the left. Neurologically, he was vigorous and normal. The lip excrescences were approximately 5 mm high and placed symmetrically on either side of the midline in the vermilion portion of the lower lip. Tiny blind dimples were present on the tip of each of these structures.

On auscultation, a holosystolic murmur and a single second heart sound were heard. There was dextroposition of the cardiac silhouette on the chest roentgenogram. Arterial blood sampling supported the clinical impression of cyanosis with severe right-to-left shunting. Corrected transposition of the great vessels, dextroposition, ventricular septal defect, patent ductus arteriosum, patent foramen ovale, and pulmonary atresia were observed at cardiac catheterization. Medical means were used to maintain the patent ductus until a Blalock-Taussig shunt could be formed on the third day of life.

The family history was negative for congenital heart disease. A distant paternal relative did have cleft palate, but this was a U-shaped cleft associated with micrognathia and probably represents the Pierre Robin malformation complex. The parents had no lip pits, lip mound, or submucous or uvular clefting on physical examination. Chromosomal studies of peripheral blood, including R banding, were normal (46,XY).

CASE 2.—This male infant was born on April 19, 1977, to a 21-year-old gravida 2, para 2 mother and a 24-year-old father. The pregnancy was uncomplicated, with quickening reported at three to four months and with the total weight gain being 7.7 kg. Known chemical exposures were limited to vitamins and iron and one to two packs of cigarettes per day throughout pregnancy.

The 2,970-g, 48-cm male infant was evaluated as a newborn at Children's Orthopedic Hospital and Medical Center because of

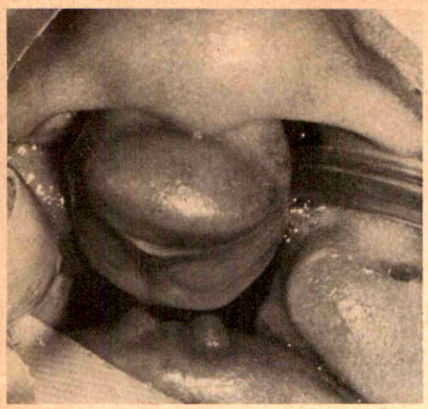

Fig 1.—Nose and mouth (case 1). Bilateral clefts and lower-lip excrescences are demonstrated. Tiny, blind dimples cannot be seen.

Fig 2.—Lip pits with surrounding mounds (case 2), as well as other facial features described in text.

multiple malformations and congenital heart disease.

Posterior cleft palate, bilateral symmetrically placed lip pits and mounds (Fig 2), prominent nasal bridge, small mandible, inferior branchial cleft remnants on the neck, prominent eyes, simple helices, hypoplastic nails, proximally placed thumbs, hypoplastic nipples, redundant posterior neck skin, dislocatable hips, and cryptorchidism with bilateral inguinal hernias were demonstrable by physical examination. Neurologically, he was hypotonic and hyporeflexic and he showed decreased reactivity; mild optic atrophy was present.

The patient had a systolic ejection murmur and paroxysmal ventricular tachycardia. Congestive heart failure developed in the week after birth and cardiac catheterization was performed. Abnormalities (by catheterization and postmortem examination) included coarctation and tubular hypoplasia of the aortic arch, ventricular septal defects, patent ductus arteriosum, patent foramen ovale, bicuspid aortic valve, subaortic stenosis, and abnormal mitral valve.

Family history was negative for congenital heart disease, clefting, or pits. Parents were free of lip pits or mounds. Chromosomal studies of bone marrow, peripheral lymphocytes, and fibroblasts (including R banding) showed a normal 46,XY constitution.

No operative intervention was undertaken, and despite medical management of congestive heart failure, the child fed poorly, failed to thrive, and died at 4 months of age of recurrent apnea. The described abnormalities and incomplete lobulation of the left lung were observed on postmortem examination.

CASE 3.—This male infant was born on March 31, 1973, to a 28-year-old gravida 5, para 5 mother and 32-year-old father. The pregnancy was free of illness or drug exposure; an older sibling had a viral exanthem at the third month of this gestation, but the illness was said not to have been rubella.

Vaginal delivery was at term. The 3,570-g, 53-cm male infant was noted to have an abnormal lower lip and, when feeding difficulties occurred, a cleft of the hard and soft palate was observed.

His case has been followed at Children's Orthopedic Hospital and Medical Center since he was 12 months of age. Problems have included lip pits, cleft palate, and congenital heart disease. The bilateral pits were removed at 12 months of age. They were nipple-like, asymmetric projections without an obvious tract, but ductile channels with collections of mucous glands were demonstrated histologically. The palate had a right-sided, V-shaped cleft of the soft and posterior half of the hard palate. It too was repaired at 1 year of age.

During his initial hospitalization, a systolic heart murmur was noted. Subsequent evaluation demonstrated a ventricular septal defect, coarctation of the aorta, and pulmonary hypertension.

In addition, the patient has growth failure, enamel hypoplasia, frontal prominence, absent upper lateral incisors, conductive hearing loss and severe articulation problems, and a deep crease between the first and second toes bilaterally. He is neurologically and developmentally normal except for the speech and language disability.

The family history was negative for lip pits or congenital heart disease. A paternal second cousin is said to have cleft lip and palate without associated anomalies. The condition of an older sister of the patient has been diagnosed as being Prader-Willi syndrome. Another sibling died perinatally secondary to a nuchal cord. The parents have no pits, mounds, or evidence of clefting. Chromosomal studies of peripheral blood, including R banding, were normal (46,XY).

COMMENT

Congenital lip pits are exceedingly rare.[1-5] These lip pits are characteristically symmetric, blind tracts in the midst of the vermilion part of the lower lip at the point where the pars glabra and pars villosa meet.[5,6] The tracts are about 2 mm in diameter and vary greatly in depth.[6] Occasionally, as in our cases 1 and 3, a tract is not easily demonstrable but, rather, nipple-like mounds are found in the same location as the more typical pits.[7] The presence of blind dimples in case 1 and histologically demonstrable tracts in case 3 supports the contention that the observed structures are homologous to more typical lip pits. Lower-lip pits must be differentiated from commissural pits at the corners of the mouth, which are common and apparently without importance.[8,9]

Lower-lip pits have been seen in only three clearly defined syndromes. Vanderwoude syndrome is characterized by lip pits; cleft lip and/or cleft palate, and hypodontia[10]; autosomal dominant inheritance; incomplete penetrance (80%); and variable expressivity.[1,5,11,12] Principal findings in the popliteal pterygium syndrome[2,3] include pterygia or tissue webs in the popliteal, crural, and oral regions; digital hypoplasia; syndactyly; genitourinary anomalies; and lip pits with cleft lip or palate. Lip pits have also been reported in two individuals with orodigitofacial dysostosis.[4] Besides these syndromes, lip pits have been found in association with clubfoot,[13] isolated syndactyly,[5,14-16] ectodermal dysplasia,[17] ankyloglossia,[18] syngnathia,[19] polythelia,[13,16] and mental retardation.[20] To our knowledge, no previous association of lip pits and congenital heart disease has been published.

Patients ascertained by the presence of facial *clefts* have a notably increased incidence of congenital heart disease.[21] In the study of Shah et al,[21] 31 of 192 consecutive patients with facial clefts had congenital heart disease. Curiously *absent* from the cases of facial clefts and congenital heart defects were transposition of the great vessels and single ventricle.[21] Ascertainment by the presence of congenital heart disease shows a

10% to 40% incidence of extracardiac anomalies.[22,23] However, extracardiac anomalies are evidently exceedingly rare in patients with transposition of the great vessels. There were no "cephalic end abnormalities" in 196 patients with transposition, in contrast to an overall incidence in all congenital heart disease patients of 6%.[23] Thus, case 1 seems to be the first recorded case of transposition of the great vessels in association with cleft lip and cleft palate.

Shah et al[21] hypothesized that the negative association between transposition and clefting is because the embryologic defect causing the heart lesion precedes palatal development by about two weeks. But Warbrick et al[24] showed that lip pits may be remnants of normally transient lateral sulci whose time of appearance (at around four weeks) and regression (complete by around six to seven weeks) are temporally coincident with conotruncal development of the heart,[21] thereby suggesting a possible embryogenic temporal relationship for the defects found in case 1. We cannot fully explain embryologically the association of malformations seen in case 1, nor will we attempt to interpret the abnormalities in cases 2 and 3.

Each of these cases represent separate, provisionally unique malformation syndromes. Although these three cases may represent different entities, they are reported together because they are apparently the first three instances of association between lip pits with cleft lip and/or palate and congenital heart disease.

This investigation was supported in part by grants GM 06730 and GM 15253 from the National Institutes of Health.

John Graham, MD, brought case 3 to our attention. M. Michael Cohen, DDS, reviewed the manuscript.

Topically Applied Testosterone and Phallic Growth

Its Effect in Male Children With Hypopituitarism and Microphallus

Ehud Ben-Galim, MD; Richard E. Hillman, MD; Virginia V. Weldon, MD

• Topical application of 5% testosterone cream for 21 days resulted in enlargement of the penis to normal size for age in five boys with normal XY karyotype who had microphallus and hypopituitarism. In four patients, testosterone cream was applied locally to the penis and in one to an area of skin in the right axilla. Serum testosterone values rose from infantile levels before the start of therapy to normal adult male levels on the last day of treatment. All patients were receiving human growth hormone at the time of therapy with testosterone. No additional acceleration of linear growth and no advance in osseous maturation occurred during or after treatment. Application of testosterone locally for this brief period is a safe, effective, and simple means of stimulating phallic growth. Our findings suggest that topical testosterone causes penile growth predominantly through its systemic action.

(*Am J Dis Child* 134:296-298, 1980)

Previous reports have documented the presence of microphallus in boys with hypopituitarism and have indicated the beneficial effects on phallic growth of systemic testosterone therapy.[1,2] Phallic growth probably depends on adequate tissue levels of dihydrotestosterone, with testosterone being converted to dihydrotestosterone in the target tissue. Immergut et al[3] in a preliminary report suggested that the observed effects of topically applied testosterone were local rather than systemic. Subsequent reports[4,5] were consistent with regard to the efficacy of topical testosterone, and suggested that the observed increase in phallic size was due to the systemic action of testosterone. We studied the effect of topical application of testosterone cream in five boys with micropenis and hypopituitarism.

SUBJECTS AND METHODS

All subjects were treated with 5% testosterone propionate in hydrophilic ointment USP. Average dosage was between 2.5 and 4.0 mg of testosterone (50 to 75 mg of ointment) applied three times a day for three weeks, on an approximate area of 9 sq cm. In four patients (1 through 4), the ointment was applied directly to the phallus, and in one patient (5) to his right axilla. Total treatment dose for each patient was less than 300 mg.

Linear growth, bone age, penile size, and plasma testosterone concentrations were determined prior to treatment, three to four hours after the final application, and six to 12 months after the conclusion of therapy. Penile size was determined by the same observer according to Schonfeld's method.[6] Height was measured with a stadiometer.

Bone age was determined on the left hand and wrist using the method of Greulich and Pyle.[7] Plasma testosterone concentrations were measured by radioimmunoassay at Bio-Science Laboratories, St Louis.

Five patients were studied. Informed consent was obtained from the parents of all patients. Patients 1 and 2, aged 6 years and 8 months and 11 years and 2 months, respectively, had panhypopituitarism and microphallus and were receiving adequate replacement therapy of growth hormone (GH), cortisol, and thyroxine. Patients 3 and 4, aged 2 years and 6 months and 7 years and 7 months, respectively, had isolated GH deficiency and microphallus and were receiving treatment with GH at the time of this study. Patient 5, aged 3 years and 8 months, had GH and adrenocorticotropic hormone deficiency and was receiving therapy with GH. All patients had severe hypoglycemic episodes in early infancy, presumably due to hormonal deficiencies.

RESULTS

As can be seen in the Figure and in the Table, the penis increased in size after therapy to within the normal range for age in all patients except for patient 4. This patient was extremely

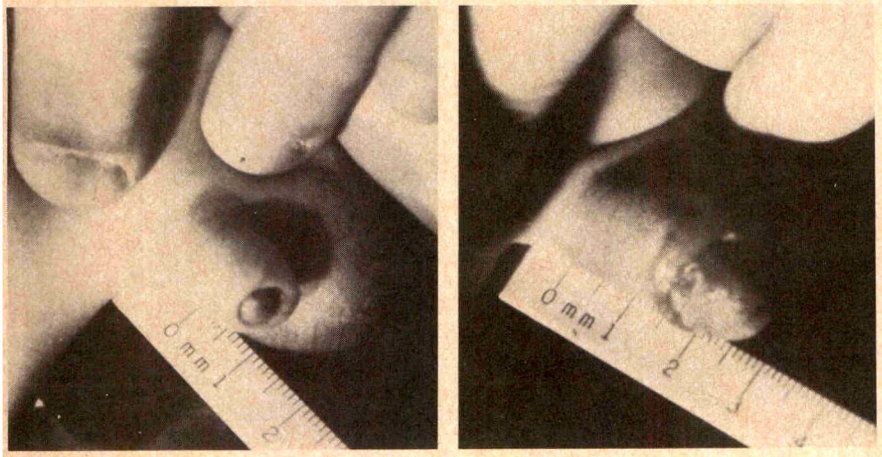
short. His penis doubled in size during treatment and became appropriate for his height and bone age, but not for his chronological age.

The desired effect was obtained at the end of three weeks of treatment in all four patients in whom testosterone was applied directly to the penis. No further change in phallic size was noticed during the follow-up period (Table). However, in patient 5, in whom testosterone was applied (in similar dosage) to his right axilla, only partial response was noted at the end of three weeks of treatment (Table), namely an increase from 1.8 to 3.0 cm in length. The penis continued to increase in size during the next three weeks after treatment had been discontinued until it reached a length of 4.0 cm, which was more than double the initial size and similar to the increase in size in the other patients. No further change in penile size was noted in this patient after the sixth week.

No change in linear growth velocity was noted in any of the patients either during the three-week period of treatment or during the follow-up period. Similarly, bone age and height age did not advance disproportionately (Table). Undesirable side-effects were minimal. In only two of the four patients who had testosterone applied directly to the penis did three to four downy pubic hairs develop. These disappeared shortly after cessation of treatment. Facial or axillary hair did not develop. Patient 5 was noted to have a slight increase in local pigmentation in his right axilla, where topical testosterone was applied. This pigmentation gradually disappeared during the three weeks after treatment was stopped. In none of the patients did acne or deepening of the voice develop. By history, daily activity and sleep patterns were not altered.

Plasma testosterone concentration was within the prepubertal level for all the patients before treatment (< 20 ng/mL) and rose during the treatment to the normal adult male range (276 to 960 ng/mL), including patient 5, whose testosterone level reached 573 ng/mL on the last day of treatment.



Genitalia of patient 5 before (left) and after (right) treatment.

COMMENT

Children with microphallus who may benefit from administration of topical or systemic testosterone fall into two major categories: those with urologic abnormalities, including hypospadius and penile cordee, and those with idiopathic hypopituitarism in whom there is usually a deficiency of hypothalamic-hypophysiotropic hormones. One should be aware that patients in the first group may have

partial or complete end-organ resistance to testosterone. Although GH may play a permissive role in promoting phallic growth, most evidence suggests that dihydrotestosterone is the primary determinant of phallic size. The knowledge that microphallus due to hormonal deficiency will respond to exogenous testosterone can be reassuring to parents, the patient, and the physician.

Two methods of testosterone administration have been evaluated: topical and intramuscular.[1-5] Each method has advantages. Lovinger and co-workers[2] described three patients similar to those in the present study whose phallic size responded favorably to treatment with 25 to 30 mg/mo of testosterone enanthate in oil given intramuscularly during a three-month period. No increase in skeletal maturation was observed, although a transient increase in growth velocity was noted. Guthrie and co-workers[1] used similar doses of testosterone cypionate intramuscularly in four patients. Although a transient acceleration in both linear growth and osseous maturation was observed in these patients initially, two years after cessation of therapy the rate of skeletal maturation and linear growth seemed to be normal. However, it should be pointed out that intramuscular testosterone in less experienced hands is not without risk to the patient. Advancement of osseous maturation out of proportion to increments in linear height may occur, as well as the onset of secondary sexual characteristics, including public, facial, and axillary hair and deepening of the voice.

Several reports have suggested the efficacy of topical testosterone when applied to the microphallus.[1,4,5] Immergut and co-workers[3] suggested that the effects of topical testosterone were local rather than systemic; however, Jacobs et al[5] found that elevated serum testosterone levels in two of their three patients supported the view that the observed effects of topical therapy are due to increased circulating testosterone levels. Further evidence that this is indeed the case was obtained in patient 5, in whom phallic growth and elevated serum testosterone levels occurred when testosterone was applied to the axilla.

Although it has been suggested that there may be psychological disadvantages to this form of therapy, the favorable response to short-term topical testosterone administration in all of the patients in this report suggests that this form of therapy may be easier to manage than intramuscular injections. There was no observed acceleration in linear growth or osseous maturation, the medication is easy to apply, the desired effect is achieved in a short time, and, finally, the cost of this form of therapy is substantially less than that of intramuscular treatment.

Elevated serum testosterone levels were observed in four of the five patients in this study. Although we do not have supporting data, we hypothesize that the repeated topical application of testosterone and the slower absorption by this route of administration results in more sustained blood levels of the hormone during the course of therapy. It is possible that this route of administration more nearly mimics the physiologic elevations of testosterone observed by Forest and co-workers[8] in the male neonate.

Recently, Read and co-workers[9] studied the effect of topical application of dihydrotestosterone in prepubertal rats. Their observations suggest that dihydrotestosterone may be an even safer form of therapy, since significant penile growth occurred in these animals without elevated plasma levels of the hormone.

These studies were supported in part by National Institutes of Health grant RR 36, from the Division of Research Resources, General Clinical Research Centers Branch.

Growth hormone for these patients was provided by the National Pituitary Agency, National Institute of Arthritis, Metabolic and Digestive Diseases, National Institutes of Health.

Brachial Plexus Neuropathy

Three Cases in Children

Lloyd M. Charles, Jr, MD, Annapurni Jayam-Trouth, MD

Brachial plexus neuropathy is an acute neurologic disorder characterized by pain, weakness, and atrophy of the muscle groups affected. Although well documented in the adult literature, relatively few cases have been reported in children. Despite the lack of knowledge concerning its etiology, and lack of an effective therapy, the long-term prognosis is excellent. It is perhaps for these reasons that spinal fluid analysis is not routinely performed during the acute phase of this illness. An evaluation of the clinical course of three children, together with epidemiologic data, suggests that early lumbar punctures and an extensive search for an infecting viral agent, notably coxsackievirus B, are warranted.

(*Am J Dis Child* 134:299-300, 1980)

Brachial plexus neuropathy (BPN) is a well-documented clinical entity, which is characterized by the sudden onset of pain, usually about the neck, shoulder, or upper arm, and is closely followed by weakness and later, depending on the severity of the illness, by atrophy of the muscle groups involved. Many cases have been associated with the injection of foreign sera,[1] routine immunizations,[2-4] viral illnesses,[5,6] or desensitizing injections,[7] but the exact nature of the disorder remains obscure. In addition, a number of families have been described whose affected members exhibit recurrent episodes of BPN, clinically indistinguishable from those cases that appear sporadically.[8]

Although the literature documents the occurrence of BPN among children, such reports have been relatively infrequent.[3,9-11] We here report three additional cases, two of which appeared within days of each other, concurrent with a local enterovirus epidemic.

REPORT OF CASES

CASE 1.—A 2-year, six-month-old, left-handed boy had had an upper respiratory infection for three days prior to the onset of specific symptoms. When fever up to 40 °C developed, he was taken to an area hospital where a diagnosis of bilateral otitis media and pharyngitis was made and where ampicillin oral suspension was prescribed. The next day, Aug 30, 1976, he refused to use his left arm and was hospitalized for evaluation. There had been no recent trauma or injections of any sort and his immunizations were complete. His birth history was unremarkable and development, thus far, had been normal. There was no family history of BPN or other forms of neurologic disease.

On physical examination, his temperature was normal and his height and weight were at the ninth and 75th percentiles, respectively. His head was held tilted to the left, and the left arm was adducted, internally rotated, and extended at the elbow. The left scapula was not winged. No appreciable voluntary movement of the left shoulder or flexion of the elbow could be elicited. Finger movements and grasp of the left hand were intact, as were pain, touch, position, and vibratory sensations. The left biceps reflex was reduced (+1), but all other reflexes were normal. Results of the complete blood cell count (CBC), urinalysis, tine test, sedimentation rate, blood culture, monospot test, serum lead and free erythrocyte protoporphyrin levels, antinuclear antibody activity and lupus erythematosus preparation, serum creatinine phosphokinase level, protein electrophoresis, and roentgenograms of the cervical spine, chest, and left arm were either normal or negative. The CSF obtained on the second hospital day showed nine WBCs per cubic millimeter (two neutrophils, seven lymphocytes), a glucose level of 54 mg/dL, and a protein value of 8 mg/dL. No viruses were isolated from the nasopharynx. Five days after the onset of symptoms, some improvement in the weakness was noted. One month later, functional recovery was complete. He was able to raise his left hand above his head and to pull himself up from a standing position. When examined one year later, the child had completely recovered.

CASE 2.—A 10-month-old male infant had been well until approximately five days before admission in July 1977 when mild symptoms of an upper respiratory infection developed. Three days after the onset of illness, intermittent fever was noted. He awoke that night crying, and manipulation of the left arm seemed to cause pain. The next morning, he was unable to move the left arm, and was hospitalized for evaluation. His history and family history were unremarkable.

When examined, his temperature was 38.6 °C. Physical findings relating to the left upper extremity were nearly identical to those in case 1, except that winging of the left scapula was present. In addition, the left hand was noticeably weaker than the right hand, and the left biceps, triceps, and brachioradialis reflexes were absent. Sensation to pinprick over the left arm and shoulder was intact. Other important physical findings included mild nasal congestion, hyperemia of both tympanic membranes, and a 2 × 1.5-cm area of hyperemia over both shoulders. A laboratory evaluation similar to that performed in case 1 showed no abnormalities. A lumbar

Reprint requests to Department of Neurology, Howard University Hospital, 2041 Georgia Ave, NW, Washington, DC 20060 (Dr Jayam-Trouth).

puncture (LP) performed on the third hospital day showed one WBC per cubic millimeter, a glucose level of 65 mg/dL, and protein value of 52 mg/dL. By the fifth hospital day, some voluntary muscle activity had returned to the affected extremity. When seen again about six months later, he had completely recovered, with no residual weakness or atrophy of the left shoulder, arm, or hand noted.

Case 3.—Three days prior to admission on June 27, 1977, a 7-year, 6-month-old, right-handed boy had pain along the left side of his neck that his mother attributed to trauma sustained while playing tag the previous day. He also felt warm so acetaminophen (Tylenol) was given. Two days later, he remained in bed stating that he did not feel well. By midday, he was unable to lift his left arm. The past history and family history were again noncontributory.

When examined, he was complaining of left neck and shoulder pain. His temperature was 39 °C. Notable physical findings included nuchal rigidity and a positive Kernig's sign. The left shoulder and arm were involved in a manner similar to the previous two cases except that winging of the scapula was not present, and left-hand function was not impaired. The CBC showed 10,700 WBCs per cubic millimeter, with 63% neutrophils, 11% bands, 13% lymphocytes, 11% monocytes, and 2% eosinophils. The CSF on admission showed an opening pressure of 17 cm H_2O, 53 WBCs per cubic millimeter (69% neutrophils, 31% lymphocytes, and no RBCs), a glucose level of 101 mg/dL, and a protein value of 23 mg/dL. No organisms were present on the smear, and the culture was negative. The remainder of his laboratory evaluation was unremarkable.

On the first hospital day, his temperature increased to 40.5 °C. After the second day, his temperature returned to normal, and the nuchal rigidity resolved. Atrophy of the left shoulder became noticeable after two weeks. Throughout the hospitalization, he complained intermittently of pain in the left shoulder and arm. Electrostimulation and ultrasound treatments were given weekly. After two months, some shoulder abduction and elbow flexion against gravity had returned. When seen at six months and again one year after the onset of illness, atrophy of the left deltoid, biceps, and spinatii muscles was still present. He was able to abduct the left arm only with gravity eliminated, and he could flex the elbow but not the shoulder against gravity and minimal resistance. The left biceps jerk was reduced as compared with the right. Throughout the interim period, no sensory loss or pain had been noted.

COMMENT

The clinical features presented by these three cases are fairly characteristic and represent the most common form of BPN, ie, unilateral involvement of the motor fibers arising from spinal cord segments C-5, C-6, and C-7. The data of Tsairis et al[10] indicate that in 89% of cases, recovery is complete after three years, regardless of the extent or severity of the initial involvement.

Elevation of CSF protein is known to occur in some cases of BPN, but the modest cellular reaction observed in two of our patients is noteworthy. Pleocytosis was demonstrated in only two of the patients cited by the literature we reviewed. In one instance, the LP was performed one week after inoculation with a combination of diphtheria and tetanus toxoids and pertussis vaccine.[3] The other patient had infectious mononucleosis, but the interval between the onset of illness and the LP was not specified.[10] In all other cases of BPN, the CSF when examined yielded normal results. The "customary" delay in performing an LP beyond the acute phase of this disease (beyond two weeks after onset), may explain the apparent lack of abnormalities. Three days after initial symptoms, case 3 showed both a mixed cellular reaction and physical signs of meningeal irritation. Finding nine WBCs per cubic millimeter in the CSF of case 1, six days after the onset of illness, is also abnormal. The CSF in case 2 showed increased protein content but no pleocytosis, but it should be noted that the LP was performed eight days after the initial symptoms.

In cases 1 and 2, the onset of neuropathy followed what seemed to be a viral upper respiratory tract infection, and although symptoms in case 3 were antedated by trauma (probably unimportant), the findings of fever, malaise, a modest peripheral leukocyte reaction with a left shift, and inflammatory cells in the CSF strongly implicate an infectious etiology. Of the cases of Tsairis et al,[10] 25% were associated with upper respiratory infection or influenza-like illness. Coxsackievirus B is suggested as playing a causative role by the epidemiologic study of Bardos and Somodska.[5] In the absence of careful viral studies, it is not possible to document an etiologic association between coxsackievirus B and BPN in our patients. However, during the months of June through September 1977, a community-wide epidemic of coxsackievirus B (particularly B2) occurred in association with several documented cases of aseptic meningitis at the Children's Hospital National Medical Center nearby (H. W. Kim, MD, oral communication). The concurrence of these phenomena, though far from conclusive, are suggestive that some as yet undetermined connection exists; and they imply that a more aggressive approach toward CSF examination in the acute phase of BPN, along with the addition of viral studies from many sites, including the CSF, may shed light on the etiologic factor of this perplexing and fairly common syndrome.

Necrotizing Fasciitis After Neonatal Circumcision

Jeffrey R. Woodside, MD

• A 6-day-old infant had extensive necrotizing fasciitis involving most of the abdominal wall develop after circumcision with a Plastibell device (Hollister, Inc). He survived this life-threatening infection after vigorous cardiovascular support, antibiotic therapy, and aggressive surgical debridement. The diagnosis, bacteriology, and management of necrotizing fasciitis are briefly discussed. The technical aspects and complications of Gomco (Gomco Surgical Manufacturing Corp) and Plastibell circumcision are compared. Strangulation and devitalization of the prepuce is invariably associated with Plastibell circumcision, and it may render neonates circumcised by this technique more susceptible to serious wound infection.

(*Am J Dis Child* 134:301-302, 1980)

Neonatal circumcision is the most commonly performed surgical procedure in the United States today. Although considered a minor operation, reported complications include infection, hemorrhage, loss of penile skin, laceration of penile or scrotal skin, injury to the glans, urethral fistula, urinary retention, staphylococcal scalded skin syndrome, concealed penis, and retained Plastibell rings (Hollister, Inc).[1-6] The experience with a newborn who had extensive necrotizing fasciitis of the abdominal wall develop after circumcision is the subject of this report. Necrotizing fasciitis has seldom been described in children, and to my knowledge, it has been reported only twice in neonates.[7-8]

REPORT OF A CASE

A 2.6-kg male infant was born by normal vaginal delivery after 39 weeks' gestation. He was circumcised without incident by the Plastibell technique at age 3 days. Two days later, his mother noticed slight penile swelling and a small amount of blood and pus on the diapers. Later in the day, the penis and scrotum turned black-purple in color. The Plastibell was removed at another hospital, and he was transferred to our institution.

He was lethargic, and he appeared acutely ill. His rectal temperature was 35.3 °C, his heart rate was 132 beats per minute, his respiratory rate was 40/min, and his systolic blood pressure was 40 mm Hg. Petechiae and multiple, 5-mm, flat, black-purple lesions covered the trunk, arms, and legs. The skin of the shaft of the penis and part of the scrotum was necrotic. Induration and slight erythema of the skin of the abdominal wall extended from the inguinal areas to the level of the umbilicus. The hemoglobin level was 14 g/dL; hematocrit, 42%; platelet count, 7,500/cu mm; and WBC count, 26,700/cu mm, with 36% neutrophils, 19% band forms, 39% lymphocytes, 4% monocytes, and 2% eosinophils. The prothrombin time was 14 s (control, 11 s); partial thromboplastin time, 40 s; fibrinogen level, 86 mg/dL; creatinine clearance, 0.9 mg/dL; BUN level, 37 mg/dL; and total bilirubin level, 8.5 mg/dL. Lumbar puncture yielded normal CSF. Gram's stain of the contents from several of the skin lesions showed Gram-positive cocci.

His condition was treated with parenteral fluids, fresh frozen plasma, human antihemophilic factor (cryoprecipitate) and platelet concentrates. Parenteral nafcillin sodium, penicillin G potassium, chloramphenicol sodium succinate, and kanamycin sulfate were given.

The nonviable skin of the entire penile shaft was surgically debrided; the glans penis and corpora cavernosa appeared healthy. Two incisions were started at the base of the penis and carried superiorly across the suprapubic area. The underlying subcutaneous tissue and superficial fascia were necrotic. These incisions were then extended superiorly into the flanks before viable subcutaneous tissue was encountered. The resultant large, V-shaped flap was extensively undermined and debrided. Multiple fasciotomies of the external oblique aponeurosis were performed, and the underlying muscles were healthy. The wounds were packed loosely with moist dressings. Postoperatively, his cardiovascular status rapidly improved, and sepsis and disseminated intravascular coagulation resolved.

Gram's stain of the surgically excised subcutaneous tissue showed a mixture of Gram-positive and Gram-negative rods and cocci. No organisms grew in an anaerobic culture of this same tissue, and the aerobic culture showed a combination of growths of coagulase-positive *Staphylococcus aureus*, *S epidermidis*, diphtheroids, nonhemolytic streptococcus, and α-hemolytic streptococcus. *Clostridium perfringens* was cultured from the necrotic penile tissue but not from the subcutaneous tissue. Culture of the contents of the septic skin emboli was sterile. A *Micrococcus* species was grown from a culture of the blood.

The extensive abdominal wound was treated with wet-to-dry dressings for further debridement. Granulation tissue was present in most of the wound after one week of therapy, and only the apex of the abdominal skin flap and a small area of the scrotum were nonviable (Fig 1). Ten days after admission, the wounds were surgically debrided of all remaining necrotic tissue, and the abdominal wound was closed primarily (Fig 2). The scrotum was closed loosely, and a split-thickness skin graft was placed around the penile shaft. The abdominal and scrotal wounds were well healed two months later (Fig 3). Minor scar revisions will be necessary, but the functional and cosmetic results should be excellent.

COMMENT

Necrotizing fasciitis is a rapidly spreading bacterial infection producing edema, necrosis, and partial liquifaction of the subcutaneous fat, superficial fascia, and superficial layer of the deep fascia. It most frequently involves the extremities and abdominal wall, and it may occur after surgery or after relatively minor trauma such as abrasions, cuts, or insect bites.[9] Meleny[10] first described 20 patients with this entity and cultured a hemolytic streptococcus from each. Culture results in more recent reports have usually demonstrated a combination of anaerobic and facultative anaerobic bacteria.[9,11] Successful culture of these bacteria requires meticulous technique, and failure of the more fastidious organisms to grow is not unusual. Patients with necrotizing fasciitis commonly have sepsis, disseminated intravascular coagulation, and hypotension, as in this patient.

Consideration of this disease in the appropriate clinical setting and a high index of suspicion are required to detect the early skin changes of minimal erythema and poorly demarcated induration. Initial treatment must

consist of cardiovascular stabilization and parenteral antibiotics effective against a broad spectrum of aerobic and anaerobic organisms. Giuliano and associates[11] recommend initial antibiotic treatment with penicillin, a penicillinase-resistant penicillin, gentamicin or tobramycin, and clindamycin or chloramphenicol. The most important aspect of therapy is surgical debridement and excision of all involved fascia and subcutaneous tissue. The reported mortality for necrotizing fasciitis ranges from 13% to 60%, with better survival after more radical surgical treatment.

Neonatal circumcision is usually performed with either the Plastibell device or the Gomco circumcision clamp (Gomco Surgical Manufacturing Corp). The Gomco clamp seals together the skin and mucosal surfaces of the prepuce by briefly applied extrinsic pressure. The Plastibell technique crushes the prepuce between a suture and an underlying bell, which drops off in five to eight days.

Gee and Ansell[12] reviewed the complications of 5,521 neonatal circumcisions performed during a ten-day period. The Gomco and Plastibell techniques were each used in approximately one half of the patients. The cumulative complication rate was 0.2%, with no significant differences between the two techniques for the various complications, except for infection. Wound infection occurred in 0.14% of the patients circumcised with the Gomco, and 0.72% with the Plastibell. All infections were initially managed with local cleansing, and each infection after the Gomco circumcision resolved promptly. However, 20% of those infected after Plastibell circumcision had fever and irritability, which resolved only after the antibiotic therapy. The Plastibell technique strangulates the prepuce and produces devitalized tissue that might be more susceptible to serious infection. The more loosely approximated prepuce after the Gomco technique would seem to permit ready egress of any purulence from between preputial layers. Thus, a wound infection of the circumcision site would tend to be locally contained.

The Committee on Fetus and Newborn of the American Academy of Pediatrics has stated that there are no valid medical indications for circumcision in the neonatal period. Nevertheless, many parents will still desire to have their male infants circumcised. Therefore, each physician performing circumcisions should be mindful that "circumcision is a surgical procedure that requires careful aseptic technique, systematized postoperative observation, and evaluation after discharge from the hospital."[13] Serious and potentially life-threatening infections after circumcision of the newborn occur more frequently after Plastibell circumcision.[12,14] This evidence suggests that Gomco circumcision is the preferred technique.

The George Armstrong Award Lecture

Are We in the Midst of a Revolution?

John H. Kennell, MD

In his book *The Structure of Scientific Revolutions*, Thomas Kuhn wrote:

> Normal science . . . is predicated on the assumption that the scientific community knows what the world is like. Much of the success of the enterprise derives from the community's willingness to defend that assumption, if necessary at considerable cost. Normal science, for example, often suppresses fundamental novelties because they are necessarily subversive of its basic commitments, but . . . the very nature of normal research ensures that novelty shall not be suppressed for very long.
>
> Major turning points in [the] scientific development [of the physical sciences] are associated with the names of Copernicus, Newton, Lavoisier, and Einstein. Each of them necessitated the community's rejection of one time-honored scientific theory in favor of another incompatible with it. They transformed the world in which scientific work was done. Such changes, together with the controversies that almost always accompany them, are the defining characteristics of scientific revolutions.[1]

For millions of years human beings had watched the stars move across the heavens, apples fall from trees, and wood burn. Ever since a major turning point in scientific knowledge was reached by investigators who studied and considered these natural events very carefully, we have had a different view of these phenomena. Over a similar span of time, human beings have observed the birth of babies and their nursing and nurturing until they were ready to lead independent lives. There have been an accelerating number of powerful influences on these vital human events, eg, birth and death in the hospital, or the myriad of shifting and changing child rearing theories. An example of the latter was the theory of John Watson in the late 1920s. He advocated a rigid approach to child rearing and advised parents to impose strict schedules on their children for feeding, toileting, and almost every other activity, including loving. He advised mothers not to kiss their children, because kissing interferes with digestion and deranges the glandular system. He advised "never hug and kiss them, never let them sit in your lap . . . kiss them once on the forehead when they say goodnight. Shake hands with them in the morning."[2] Have factors affecting human development, such as the child rearing theory of the month, received the scrutiny, investigation, and evaluation that has been directed to the stars and planets, to the principles of chemistry, physics, and mathematics?

Patterns of family life, human development, and the customs surrounding the two major life events, birth and death, were modified slowly and gradually until the start of the revolutionary industrial and social changes that began about the time George Armstrong opened his clinic for poor sick children in 1769. As a result of technologic progress and the remarkable advances in pediatrics and obstetrics, we all know that many more babies and mothers survive, but we are faced with an overwhelming array of individual, family, and societal problems.

Is it possible that we have discarded or overlooked treasures of evolutionary wisdom for human development in the rush of progress? The side effects on infants and parents of most of the innovations of the last 200 years have never been studied scientifically.

Are we in the midst of a scientific revolution that can blend evolutionary patterns from the past with advances in the future? Are we suppressing novelties, either old or new, that do not fit with our normal science, our present day US view of what the world is like?

Today we honor one of the major innovators in medicine, George Armstrong. He was suppressed and unappreciated because he had a novel solution to the problems of sick children. Earlier in this century, Sir George Still called the opening of Armstrong's dispensary "the most important step ever taken [in England] towards the care of sick children."[3] The effects of this physician's efforts

have extended to this day and this hour, and have stimulated me to consider this question: Who shows the way and who follows? How we answer this question will certainly help us describe this modern revolution.

BREAST-FEEDING

During the 1970s, I have had the good fortune to go to a developing nation on many occasions. What I have seen has raised many questions that I would like to share with you.

First, who leads the way and who follows in regard to breast-feeding? The adults and children in the Mayan Indian village of Santa María Cauqué in the Guatemalan highlands were studied meticulously by Leonardo Mata and Juan Urrutia for a decade and a half.[4] The vast majority of mothers would be considered malnourished by our standards, but almost every mother in that village was able to breast-feed successfully for a mean period of two years. The clinically healthy mothers had at least three or four parasites or bacterial pathogens in their stools, some were ill with conditions that we would consider contraindications for breast-feeding, such as mastitis, acute respiratory infections, or shigella or salmonella enteritis. Even under these conditions, mothers do not stop breast-feeding. These women had no watches or clocks to time the intervals between feedings and put no soap or ointments on their nipples. They fed the baby when the baby wanted to suckle and as often and as long as the baby wished. They slept with their infant so nursing continued every few minutes through the night. It is this frequent nursing that appears to assure an abundant milk supply and provides maximum contraceptive effect. It is well-known that breast-fed babies have only one fourth to one fifth of the intestinal and respiratory infections of bottle-fed babies.[5] In a recent study, the average rural mother produced greater quantities of milk than the average poor or even well-to-do mother in the city. I wonder if these Mayan Indian mothers, whose practices have probably changed little over the last 1,000 years, do not have much to teach us about assisting nursing mothers and infants in the United States; for example, about the frequency of feeding an infant.

Fig 3.—Newborn baby, mother, and grandmother inside Indian home in village of Santa María Cauqué in Guatemalan Highlands (from Klaus and Kennell[21]).

The babies of our human ancestors were probably carried and nursed frequently for over 99% of our species' existence (Fig 1). For more than a million years, they lived as hunters and gatherers (from recently discovered foot prints, Mary Leakey says 3.6 million years [*National Geographic* 155:446-457, 1979]). They had the same skull, the same bone structure, and

perhaps some of the same behavior patterns as humans today. The small square in the lower right-hand corner of Fig 1 indicates the approximately 10,000-year period since the agricultural mode began, and the 200-year span of our present industrialized society is represented by an almost invisible dot, a period too short for evolutionary adjustments to occur. Other evidence suggesting that human mothers and infants may do best with frequent feedings is found in Ben Shaul's study of more than 100 mammalian milks[6] (Fig 2). Note the high fat and protein content of the mammals who feed their young at intervals of five to 15 or two to four hours (for example, deer and dogs), the decidedly lower fat and protein content of those who feed almost continuously (such as goats and nonhuman primates), and the still lower levels in the human. Was the human infant meant to breast-feed continuously?

Second, let's look at a series of observations in Guatemala in regard to the remarkable immunologic properties of breast milk. Figure 3 is a photograph of the inside of a Guatemalan home in the village of Santa María Cauqué with a newborn infant, her mother, and grandmother. Four days after this visit, a well-nourished American pediatrician who visited the home was laid low by crampy abdominal pains and watery diarrhea. On recovery, the pediatrician returned to the home and saw that the baby had remained completely healthy, as is true of most of the newborns in that village for the first three months of life. Neonatal mortality in this village is high (37 per 1,000 live births), mainly because of the high proportion of infants of less than 2,000 g birth weight. However, a birth weight of 2,750 g reliably predicted survival for the first three months.[4] In 15 years, there has been almost no morbidity in the first 28 days in infants born in the village, compared to many serious problems due to infection in infants born in the hospital. This can now be explained by several mechanisms. As you are probably aware, when a mother has an infection, such as pathogenic *Escherichia coli* enteritis, sensitized

Fig 4.—Mother carrying her infant on her back as she goes about her daily activities of tending sheep and llama, and spinning wool in Andes near Cuzco, Peru.

cells in her gastrointestinal (GI) tract migrate to the mammary glands to produce specific protection from the time of birth on. This protection is provided by secretory IgA antibodies in the mother's milk, which are not destroyed by proteolytic enzymes in the GI tract. Thus, we may be able to look to rural areas of developing countries for information about the process of breast-feeding and for evidence of its beneficial effects.

THE ROLE OF BODY CONTACT

Most travelers are amazed to note that they almost never hear a baby cry when they visit a developing country. It is particularly impressive to a US pediatrician who cannot remember a day when he did not have a phone call from a mother concerned about her crying baby. This leads to a third series of observations and questions about infant care. Was the human infant meant to cry except when in pain? Is crying due to a need for warmth, contact, and stimulation? The lack of infant crying in developing nations is often attributed to malnutrition, but many well-nourished, healthy, active, and responsive infants in these countries do not cry. As shown in the photograph of a mother from Cuzco in the Andes Mountains of Peru (Fig 4), the practice of our ancestors, the hunters and gatherers, for hundreds of thousands of years of carrying the baby on the mother's body and sleeping with the baby at night is still carried out in developing countries, which have a settled agricultural existence. The woman in Peru shows it is possible in some cultures for the mother to provide stimulation and breast-feeding for her infant while she is working. She is tending a flock of sheep and llama at the same time that she spins wool and provides the infant with stimulation and close contact. In most children's hospitals in the United States, about 1% to 3% of the admissions are for infants suffering from nonorganic failure-to-thrive, who often respond dramatically to human contact and stimulation. Does this practice of carrying the baby on the mother's body have relevance for us in the United States for failure-to-thrive? Does it have relevance for us in the United States for colic? For sleep problems? For separation problems? Who leads the way and who follows?

A fourth observation relates to tactile sensitivity to the infant's needs. Sierra Leone is one of many countries where every young mother is expected to be able to carry her baby on her body all day and detect the small changes in breathing and body movements that precede urination and defecation, so by one week she is able to care for her baby with no soiling of her clothes. She is considered a poor mother if she makes any misjudgment. For Eskimo mothers, a miscalculation could be disastrous because of wind-chill factors that result in freezing of the skin with exposures of less than 30 s. Mothers and fathers in the United States seldom learn how to pick up tactile signals from their babies and to achieve this state of fine-tuned responsiveness to the baby's needs. Christine Cooper reported in conversation (January 1978) that when mothers in Sierra Leone come to the clinic saying their infant has a urinary tract infection, they are almost invariably correct. How do they know? The baby would urinate frequently, and the usual signals were changed so the mothers's clothing would be soiled.

I am describing these patterns of behavior in other cultures to demonstrate principles, not to recommend their application in the United States without careful study. In no way do I

recommend skin-to-skin contact for the diagnosis of urinary tract infections, nor do I believe that mothers in the United States are ready to use the fine-tuned responsiveness to an infant without diapers in a carpeted home. However, we may get valuable hints and insights from observing different patterns of care in the context of evolutionary development. And then these can be studied scientifically. In Guatemala, for example, it may be possible to sort out elements that are related to the Indian's life-style of poverty, poor nutrition, and limited education, and to distinguish these from other components, such as success with breast-feeding, the children's joy in family and community life, and the ability of the adults to organize the community and rebound from catastrophies, such as the devastating earthquake in 1976 that destroyed all the adobe homes, killed 78, and injured 357 among 1,500 people in one village.[4]

CHILDBIRTH

Back in the United States, there is another set of statistics that reflects a growing concern of all of us. One million 15- to 19-year-old women become pregnant each year, or one tenth of all women in this age group. Thirty thousand girls younger than 15 years become pregnant and 13,000 give birth each year. The following observations concern preparation for motherhood and support for the pregnant teenager.

In the United States, the limits of adaptability of the teenage mother may be exceeded by the medicalization of childbirth, the provision of multiple clinics, and a shifting assortment of physicians and nurses during her pregnancy and delivery. Let us compare this with what happens in the village of Santa María Cauqué. Every child will be involved with the care of younger children, and every girl, through daily practice and on-the-job training, becomes expert by 12 years of age in the activities of a woman and mother in that culture: cooking, laundering, and child care. Childbirth in nonindustrialized societies is regarded as an integral part of ordinary family life. When the new mother in Fig 4 was 15 years of age, she had been going with a boy for about a year. When it was clear to her boyfriend's parents that a strong interest was developing, she was invited to help her future mother-in-law for several months to become accustomed to the family and their ways. Then, after a fiesta, the boy's parents asked him to bring the girl to live with them and share his bed from then on. Due to malnutrition, the onset of menstruation and ovulation is late, with the average age of menarche at 14½ years. Usually the first baby is born one year after marriage. By the time this girl was invited to live in her boyfriend's home, she was thoroughly familiar with all the activities of a woman and mother in that society. With the first sign of pregnancy, the boy's mother called in the native midwife. In Santa María Cauqué, no change in diet or activities is recommended. However, in other cultures the young mother-to-be is expected to adhere to a whole series of prescribed and proscribed activities with which everyone in the village agrees completely because they have been standard for centuries. Usually there are certain dietary restrictions. In some communities, there are recommendations of increased physical activity, in others reduced. In some villages, sexual intercourse is strongly encouraged through pregnancy, as it will lead to a stronger baby; and in others it is prohibited for the same reason. For many of the aches and pains associated with the pregnancy, the native midwife or the native healer has ready answers. In Santa María Cauqué, the woman works almost to the time of delivery.[4] Labor is short for primiparous deliveries, with a mode of four hours in 429 deliveries, a shorter time than stated in most textbooks. Few had a labor of more than eight hours. Almost all deliveries are in the kneeling position on a dirt floor or mat in the home, surrounded by supporting family members. There has been a remarkably low incidence of breech deliveries, 0.7% in contrast to the 2% or more quoted in most textbooks.[4] Does this give us ideas about what we should study in birth centers? There is no doubt that modern obstetrics has made remarkable advances and we do not want to lose the gains that have been made, but it is interesting to note that no preeclampsia or eclampsia were observed in any patient in Santa María during the 15 years of study. *No* cases of puerperal fever and *no* deaths of the mother during childbirth or puerperium occurred. Who shows the way and who follows?

SUPPORTIVE PERSON DURING LABOR AND DELIVERY

In an age of electronic monitoring of the fetus during labor, is there anything that we can learn by observing the effect of support during childbirth? This question leads to another set of observations. Consistency of care during pregnancy, labor and delivery, and the postpartum period is an important tradition in the villages and rural areas of many developing nations. In all but one of 38 cultures that have been studied by anthropologists, there is a woman who remains with a mother during labor and assists at birth. In Santa María Cauqué, the native midwife, both grandmothers, the husband, and occasionally the father-in-law are present. It is interesting that no children are allowed, as is true in most cultures, but they know what is happening. In 98% of all cultures, there is a tradition of postpartum confinement of the mother and baby together, and more than 50% of all societies will not allow a male doctor to be present at delivery. Ann Oakley[7] says that "the transition from control by laywomen to control by professionally trained men is the most crucial change that has occurred in the management of childbirth in industrialized society over the last 100 years."[7]

Let's look at a study in a busy obstetric hospital with a delivery system that was established by doctors and nurses from the United States. In a recent, carefully controlled study in Guatemala City, women who labored alone, which was the usual routine, were compared with women, randomly selected, who had an untrained woman present with them throughout labor. The presence of a supportive woman in a hospital setting signifi-

cantly reduced the length of labor from 19 to nine hours, strikingly decreased the incidence of obstetric and pediatric complications, such as meconium staining and fetal distress, and strongly influenced the behavior of the mother and her infant after delivery.[8]

You might be interested to know that in two maternity hospitals where separation of mother and baby was routine for the first 12 to 24 hours after delivery, all the mothers in these hospitals are now given their babies to keep and care for throughout the hospital course within one to two hours after delivery. This has resulted in the elimination of the central nursery and the provision of space for medical student and nursing student study and teaching sessions.

Fig 5.—Mothers feeding and caring for their own premature infants in Baragwaneth, South Africa. (Courtesy of Eric Kahn and Sam Wayburne from Klaus and Kennell[21]).

FAMILY PARTICIPATION IN HOSPITAL CARE

Another series of observations relate to family participation in the care of sick people. When we first traveled around Guatemala, we were told by a driver that the Indians were not very smart. There was a new hospital with the latest in medical, surgical, and operating room equipment. This hospital had restrictions on visiting times and on the number of visitors. The driver commented that the "dumb Indians" did not come to that hospital, but continued to go to the old adobe hospital in that region. The building was too small for the large number of patients who came for care, so they extended out into the surrounding area in uncovered and unprotected ward-like groupings. In this hospital, families lived-in with patients to provide for their care and to cook for them. Apparently this was important enough to the families that they were willing to give up the advantage of a more modern hospital.

Family participation also includes involving parents in the care of premature infants. In 1954 in Baragwaneth Hospital, South Africa, Eric Kahn and Sam Wayburne described their experiences with mothers living-in in the hospital and breast-feeding their infants (Fig 5). They showed a significant increase in the survival of the infants, with statistics comparable to the best university centers: and at a reduced cost.[9] In Ethiopia, Nebiat Tafari showed that by asking parents of premature babies to live-in the hospital and care for and breast-feed their infants in the premature nursery, he was able to care for three times as many infants, the mortality in the nursery decreased dramatically, and the number of surviving infants increased 500%. With care by parents, the cost of the care of an infant in his unit decreased from $120 in 1970 to $40 in 1972.[10,11] Who leads the way and who follows?

MEDICAL RECORDS

No talk by an old ambulatory pediatrician could avoid some mention of medical records. Is it possible that there are even some insights about records to be gained from developing countries? In his book, *Pediatric Priorities in the Developing World*, David Morley[12] describes the home-based record and emphasizes that the child's medical records are best entrusted to his mother from the time of birth or from the first visit onwards. From his long experience with an "under 5 clinic" and an "at risk clinic," he reports that the child's record is available at the time of a contact at home, in the clinic, or in the hospital in well over 95% of the visits and that there the loss of medical records is only about 1% per year, compared with losses of 5% to 10% in US clinic filing systems. When the mother brings the record, patients can be seen immediately. Should we follow, or at least study this alternative method of keeping records?

Here I would like to point out a new untapped source of research information and concepts about children. The Society for Research in Child Development (SRCD), which met in March 1979 in San Francisco and considered a wide range of fascinating topics. One was a study on "Sex Hormones in Umbilical Cord Blood: Their Relationship to Behavior at 4 Years," which showed a correlation between levels of testosterone and estrogens and rough-and-tumble play at age 4 years. (It was not the activity, but whether the child was the attacker or the one attacked that was related to the hormone level.) There were research reports on "Children's Understanding of Illness." "Peers as Therapeutic Agents," "Helping by 2-Year-Old Children," "Separation Distress Over the Life Span," "Pros and Cons of Infant Day Care," and "A Prospective Study of Nonorganic Failure-to-Thrive." An increasing number of pediatricians from the United States and around the world have found these meetings exciting and valuable. The studies of children by investiga-

tors from disciplines such as sociology, anthropology, and ethology may turn out to be as fundamental for ambulatory pediatricians as the traditional basic sciences have been for other pediatric subspecialists. The members of the SRCD may show us a new way.

PEDIATRICS LEADS THE WAY

At this point I will make a major shift and now consider where pediatrics has led the way and others have followed.

First, let's consider what pediatrics has contributed to adult medicine. Of course, pediatrics did arise in part from adult medicine and has been influenced by its practices and teachings, but what have we in pediatrics offered or what can we offer to our colleagues in adult medicine? The basic principles of fluid and electrolyte therapy were discovered and applied by pediatricians. The investigations of Gamble, Darrow, Wallace, and others resulted in the saving of thousands of infant lives throughout the world, but also made possible major improvements in the care of adults: for example, the successful treatment of cholera. The extremely important commitment of pediatricians to preventive medicine has brought an array of immunizations to adult medicine, as well as many other concepts of prevention.

The complex features of growth and development that appeared for several decades to be peculiar and limited to the pediatric age range have gradually influenced adult investigation and care in the biochemical, immunologic, and psychologic areas, with an increasing appreciation of changing fluid and electrolyte needs, the changing susceptibility to infection, and the significance of developmental stages, periods of crisis, and life-span studies, as emphasized in *Seasons of a Man's Life* by Daniel Levinson[13] and *Adaptation to Life* by George Vaillant.[14]

The benefits of a neutral thermal environment for low birth weight infants shown by pediatricians, starting with the studies of Silverman et al,[15] the concepts of temperature control they developed were picked up by those caring for adults and applied eight to ten years later to burn patients, and then later on to older cardiac patients, with improvements in outcome.

Fig 6.—Portrait of Ralph Izard, aged 12 years, by Jeremiah Theus, 1753. (High Museum of Art, Atlanta, Ga; anonymous donor.)

THE FUTURE AND THE PAST

What about the future? Who shows the way and who follows? Has pediatrics developed other aspects of care that can be of benefit for adult patients? I believe the answer is an emphatic "Yes." Let's consider a few possibilities.

Starting in a small way in a few hospitals, Child Life or recreational or play programs have made such a great improvement in the lives of hospitalized children. These programs provide an opportunity to play and express fears and anger, and prepare the child for operations, anesthesia, and procedures; there has been an explosion of these programs for hospitalized children and for children coming to ambulatory clinics.

Let me take a slight detour for a minute. If you have enjoyed the paintings by hospitalized or sick children, or if you find, as I do, that it is valuable to look at the past to get a view of the future, then I recommend wholeheartedly that you visit the Junior Gallery at the Atlanta High Museum of Art. There you will find an exhibit called "Children in America," which illustrates the changing images of childhood from colonial days to the present. The paintings span the years, from the time George Armstrong opened his clinic 210 years ago to the present. If you go, you will see paintings such as the one entitled "Ralph Izard" (Fig 6), painted in 1753.

Eighteenth-century artists painted sober, stiff youngsters, dour in face, erect in posture, adult in demeanor. Life was severe: one half of all youngsters died before the age of ten. Children were hurried into adult responsibilities. Here Ralph, 12 years old, is painted as lord of the manor that he inherited at age 7 years, stiffly gesturing toward his property. Another picture, "Wilson Children," painted around 1860, shows boys and girls dressed alike. Parents had begun to regard play as a natural, even educational, activity, so toys began to appear on artists' canvases, and children were shown in more informal poses. Another picture is called "Shoe Shine Boy," and shows the romanticized view of working children in the late 19th century, the up-from-nothing, sentimental, Horatio Alger success story. The exhibit also has pictures of the grim life of young children laboring in a mill or factory.

Please think for a minute about your image of the pediatric and the adult divisions of your hospital. Like the paintings of the children, I believe these divisions reflect social history or society's view of the care of children and adults. If you or adult members of your family have been hospitalized recently and benefited from modern surgical and technological advances, you may be aware of the need for an "Adult Life Program" in hospitals, similar to Child Life Programs. Over and over, we are impressed that our nursing and pediatric colleagues do not understand their own disease or treatment when they are hospitalized, or are afraid to ask. Adults have vivid fantasies, just as children do. Adult life workers and an adult life program could be of great value in these units, but shouldn't they be provided for all adult patients, even those who may

only be going through elective studies, who need preparation, information, and support? Shouldn't one person be provided to support each adult whose family or friends do not do this?

Members of the Ambulatory Pediatric Association have been leaders in the introduction and support of Child Life Programs. They have also pioneered in the development of programs for parents to live in the hospital with their young children. In turn, these have usually led to the establishment of parent discussion groups and more involvement of the entire family in visiting the hospital and caring for the sick youngster. Sir James Spence at Newcastle-upon-Tyne and James Robertson and Dermod McCarthy in Amersham, England, were innovators with these concepts and showed that children could be hospitalized with a minimum of disturbance if their parents lived in with them, in contrast to the child who was hospitalized alone.[16,17] The Care by Parent unit started by Vernon James[18] and further adapted by Morris Green stimulated the introduction of a large number of similar programs.

Does this have application to adults? I think it does. In reaction to the technological and impersonal aspects of institutional care and a torrent of requests from young, healthy couples, hospitals in almost every large city in the United States have opened homelike birth centers, where a woman in labor can have the father, friends, and any members of the family present during labor and delivery, can bring their favorite pictures and music, and can make some decisions about her care. These enthusiastic, energetic young adults have rocked the obstetric establishment through their insistence on a reconsideration of firmly held practices, such as the mother's position during labor and delivery, the routine use of episiotomy, and elective induction with pitocin. No hospital supply manufacturer in the United Kingdom or the United States has yet developed a double bed for hospital use, so it has been necessary for centers to innovate. The concept of allowing the father and mother to be together in bed with their newborn baby has set off an explosive reaction by many male doctors that somehow this is not right. (When fathers are allowed to live in with their wives, they do get into bed, and one cannot be certain about what goes on.) But seriously, a place for fathers in maternity divisions is important for many reasons.

Fig 7.—Future mothers in village of Santa María Cauqué.

Briefly, I would like to share the contents of a film of an interview of a couple who had a baby with Down's syndrome.[19] The mother describes vividly how important it has been for her husband to live in the hospital with her. In spite of the permission of the Chief of Pediatrics, the Chief of Obstetrics and the Chief of Nursing, the staff could not find a bed in this large hospital of 1,200 beds! It is not easy to bring in a new concept.

If those involved in adult medicine will follow the lead of ambulatory pediatricians and make it possible for adults to live in and provide care for family members, they will encounter some of the same problems of crowding and confusion that accompanied the introduction of unlimited visiting and parents living in with their children on the pediatric divisions. However, there is little doubt that there will be benefits for the adult patients as there are for young children. Just as families have taught us much about the care of children, so also, families will teach those in obstetrics and adult medicine and surgery much about the care of adults.

WHO LEADS AND WHO FOLLOWS?

There are many questions for us to consider. We view a pregnant woman in one fashion and the Indians and other preindustrial groups view her in another. Who leads whom? Should mothers sleep with their infants? Should mothers be encouraged to carry their babies on their bodies? Or is this impractical for women in our society? Should pregnant mothers be encouraged to keep active physically almost to the time of delivery? Is there a way to involve young women and men in child care in the home, or in school? Should we make a drastic change in hospital care and do as we do in ambulatory care, turn over full responsibility to the family for feeding and bathing the hospitalized child and giving oral medications?

Would the presence of a supportive woman with every mother laboring and delivering in the United States decrease the need for obstetric interventions and help prevent neonatal asphyxia? Should we entrust children's medical records to their parents?

What novelties are we suppressing? Are we at a major turning point in scientific development? What does it

mean that some of the methods of birthing and child care in developing countries do not fit in with what we consider the best modern style of living? I do not have the answer to these questions.

Before concluding, I want to make it clear that in this International Year of the Child I am not ignoring the great scientific advances in North America. I want to emphasize that I have described these patterns of behavior in other cultures so that we might look for principles, not to recommend their application in the United States. I do not want to suggest that we go back to what is going on in Santa María Cauqué (Fig 7), but we can get hints and ideas from preindustrial cultures that may open up vistas in our understanding. Modern medicine has made many significant advances, but a few of these may be steps backward. Our scientific revolution may hinge on choosing the most promising components from our evolutionary past and testing these against our modern practices, in long-term studies, with consideration of the broadest ramifications. Then we will determine who shows the way and who follows.

This investigation was supported by Public Health Services grants MCR390337-04-0 and MRP-HD 11089-02; and grants from the Research Corporation, William T. Grant Foundation, Thrasher Research Fund, and the Robert Wood Johnson Foundation.

Figure 2 is reproduced with permission from WB Saunders Co. Figures 3 and 5 are reproduced with permission from CV Mosby Co, St Louis.

I must express my thanks to some of the persons who made it possible for me to receive the George Armstrong Award. Charles Janeway, MD, and William Wallace, MD, gave me my start in Ambulatory Pediatrics and academic medicine; Gustavo Casteñada, MD, Leonardo Mata, MD, Roberto Sosa, MD, and Juan Urrutia, MD, introduced me to Guatemala and its people; Charles Q. McClelland, MD, and William T. Staples, MD, gave my patients care whenever I was away on my research travels; my colleagues in neonatology and behavior, particularly Marshall Klaus, MD, helped me with many of the ideas presented here. Finally, my wife Peggy and my children have faithfully put up with the pressures on family life from research, teaching, and patient-care commitments.

Radiological Case of the Month

Lionel W. Young, MD;
Contributed by Herman Haimovici, MD; Richard J. LaVigne, MD; Terry T. Howard, MD

From the Departments of Radiology (Drs Haimovici and LaVigne) and Obstetrics and Gynecology (Dr Howard), Medical Associates, Chelmsford, Mass.

Reprint requests to Department of Radiology, Children's Hospital of Pittsburgh, 125 DeSoto St, Pittsburgh, PA 15213 (Dr Young).

A 34-year-old woman was sent for ultrasound examination "because [of] a disproportionally large uterus for the dates." Physical examination and previous medical history were unremarkable. Her obstetrical history was two normal pregnancies from a first marriage and from a second marriage, a spontaneous abortion and a stillborn baby at 25 weeks with harelip, cleft palate, and low-set ears. The ultrasound examination (Fig 1) shows a fetus of approximately 28 weeks' gestation, with a large mass around the head and the neck. Three weeks after the ultrasound examination, fetal death occurred and a cesarean section was performed.

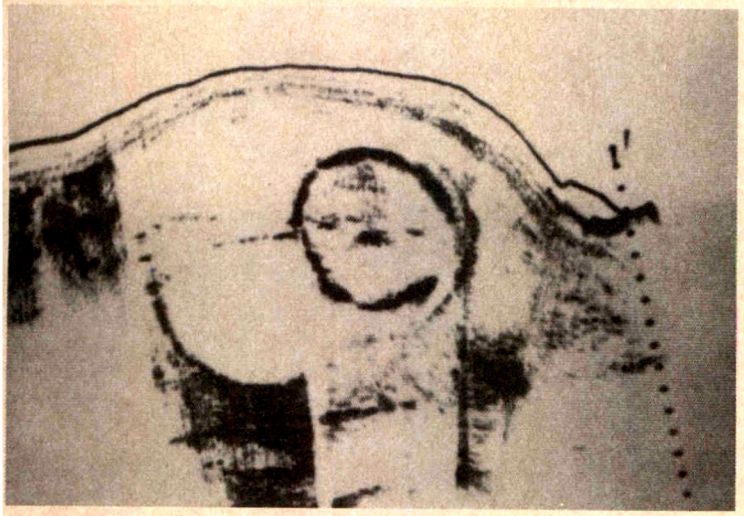

Figure 1.

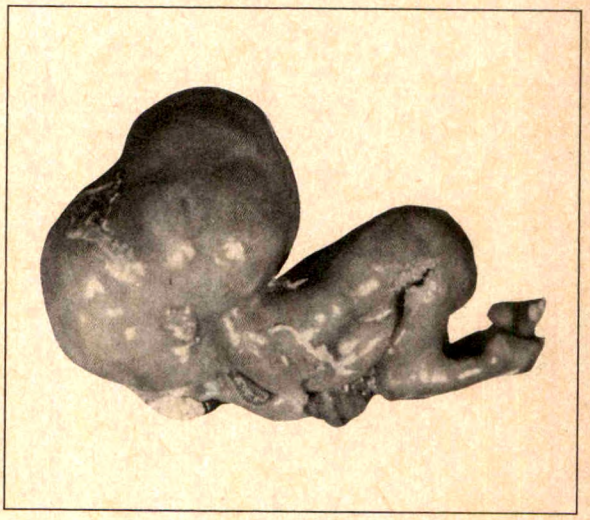

Figure 2.

Denouement and Discussion

Fig 1.—Longitudinal scan 2 cm to left of midline.

Fig 2.—Fetus with large hygroma involving neck and posterior aspect of head.

Hygroma (Cystic Lymphangioma): Diagnosis by Ultrasound

Hygroma's are congenitally modified lymphatics presenting as a large single cavity or as multilocular fluid cavities. Most often they develop on one side of the neck, but may be found in other locations. The cysts, filled with clear straw-colored fluid, are lined by a single layer of flat endothelial cells and surrounded by connective tissue and smooth muscles. They are not compressible and not visibly connected with lymphatic channels. They may increase in size after birth because of the increased secretion of fluid. Abortion, as in this case however, is not a rare occurrence. Evacuation of fluid gives only temporary relief and unless the endothelial wall is completely destroyed the fluid will reappear. As the cyst enlarges, rupture and bleeding followed by calcification and fibrosis may occur.

With the gray scale and real-time modes of ultrasound, prenatal diagnosis of cystic hygroma after 14 weeks of pregnancy is possible, as demonstrated in our case. A large echo-free and septate structure is very suggestive of a hygroma.

Differential diagnosis should include failure of proper closure of the neural tube with resultant spina bifida and meningocele. Strict posterior location of the cystic mass and an associated increase of α-fetal protein in the blood and amniotic fluid are hallmarks of this diagnosis. A branchial cleft cyst due to the failure of closure of the embryonic branchial cleft appears also as an echo-free area over the lateral side of the neck, but is usually much smaller in size. From an obstetrical point of view, prenatal diagnosis of a large hygroma is important because it requires cesarean section.

Donald Agostinelli, MD, provided the photograph of the fetus.

Looking for a physician?

Here's how to quickly find the perfect fit for your position.

If you're looking for a physician with a specific specialty, the new **AMA Physician Placement Register** is the best source of information on the physicians available. Published quarterly by the AMA Physicians' Placement Service, the Register is the only comprehensive national listing of physicians seeking new practice opportunities.

Fast turnaround! The Register is mailed within 24 hours of receipt of your request. After receiving your selections of the physicians on whom you want further information, full-page computer printouts on each physician will be sent to you within ten days.

New.AMA Opportunity Placement Register. As an adjunct to the Physician Register, a coded synopsis of your opportunity will be included in a companion Opportunity Register. Physicians seeking relocation use this Register the same way you use yours, providing you with important additional exposure.

Send for your Register today!

Get them on their feet again!

When winter colds are at their worst, Naldecon® is at its best!

(antihistamine/decongestant)

Winter colds can get even the best of sports down. But Naldecon® (antihistamine/decongestant) can get them up and going again with fast symptomatic relief!

With balanced formulation for maximum relief and minimum side effects.

Naldecon combines antihistamines from two chemical classes, as well as two decongestants, to offer prompt symptomatic relief and minimize side effects. That's why it's the ideal choice for busy, active patients who aren't going to let a cold stop them.

An ethanolamine for long-lasting antihistamine activity

An alkylamine for minimal antihistamine drowsiness

Phenylpropanolamine for prolonged decongestant effectiveness

Phenylephrine for additional decongestant action with little or no C.N.S. stimulation.

With a unique tablet designed for easy titrating and hours of sustained relief.

With Naldecon tablets, adjusting dosage without losing the convenience of sustained relief is a snap! The unique Naldecon tablet is scored so that just a little thumb pressure on each half of the tablet breaks it neatly in two. Half tablet or whole, the outer layer rapidly dissolves for prompt effectiveness and the slow-release inner core provides additional hours of relief.

With enough dosage forms to keep the entire family skiing.

Naldecon's full line of forms for all ages includes "kid-tested and flavor-approved" pediatric liquids.

- Adult tablets and syrup.
- Pediatric syrup for infants and children, 6 months to 12 years old.
- Pediatric drops for infants and children, 3 months to 6 years old.

Naldecon® salutes the world's best.

XIII OLYMPIC WINTER GAMES LAKE PLACID 1980

The world's best winter athletes gather in Lake Placid this year for the quadrennial spectacle of the Olympic Winter Games. Bristol Laboratories takes great pride in having Naldecon designated Official Supplier to these XIII Olympic Winter Games.

We salute the splendid amateur athletes whose memorable feats are once again an inspiration to all of us who have trouble staying on our feet in the winter.

Naldecon®

(antihistamine/decongestant)

Naldecon®
(antihistamine/decongestant)

Official Supplier to the XIII Olympic Winter Games in Lake Placid, New York.

XIII OLYMPIC WINTER GAMES LAKE PLACID 1980

Only Naldecon® offers the winter cold sufferer the effectiveness of *two* antihistamines and *two* decongestants, proportioned to minimize their undesirable side effects.

Naldecon® has:

- **Staying power.** Sustained release: an outer layer fo immediate relief, an inner core for hours more.
- **Flexibility.** Dosage forms for all ages and a unique scored tablet for fractionalized dosage, without losing the sustained release.
- **Balance.** Formulated to provide maximum effective ness with minimum side effects.

NALDECON® Tablets, Syrup, Pediatric Drops, and Pediatric Syrup For Oral Use Only

5600DIMO-11 1/78

DESCRIPTION:

Each sustained-action tablet contains:	For immediate action	For delayed action	Total content
Phenylpropanolamine hydrochloride	20.0 mg.	20.0 mg.	40.0 mg.
Phenylephrine hydrochloride	5.0 mg.	5.0 mg.	10.0 mg.
Phenyltoloxamine citrate	7.5 mg.	7.5 mg.	15.0 mg.
Chlorpheniramine maleate	2.5 mg.	2.5 mg.	5.0 mg.

Each teaspoonful (5 ml.) of syrup contains:

Phenylpropanolamine hydrochloride	20.0 mg.
Phenylephrine hydrochloride	5.0 mg.
Phenyltoloxamine citrate	7.5 mg.
Chlorpheniramine maleate	2.5 mg.

Each pediatric formulation contains the following ingredients:	Pediatric Syrup each 5 ml. contains:	Pediatric Drops each 1-ml. dropper contains:
Phenylpropanolamine hydrochloride	5.0 mg.	5.0 mg.
Phenylephrine hydrochloride	1.25 mg.	1.25 mg.
Phenyltoloxamine citrate	2.0 mg.	2.0 mg.
Chlorpheniramine maleate	0.5 mg.	0.5 mg.

ACTIONS: Naldecon is useful for the relief of nasal congestion associated with pollen allergy and minor infections of the upper respiratory tract (the common cold, nasopharyngitis, acute and chronic sinusitis). Naldecon tablets are compounded with half of each ingredient in the outer layer for immediate action and the remainder in the slowly disintegrating core for a sustained effect.

The actions and uses of individual ingredients in the formulation are as follows:

Phenylpropanolamine Hydrochloride

Phenylpropanolamine hydrochloride[1] acts similarly to ephedrine. It is effective orally for the symptomatic control of allergic manifestations, such as perennial hay fever and bronchial asthma. Its action is more prolonged than that of ephedrine, and it is not so apt to produce anxiety complex as is ephedrine.

Phenylephrine Hydrochloride

Phenylephrine hydrochloride[2] is a more powerful vasoconstrictor than synephrine tartrate. When administered orally, it is a vasopressor and relatively nontoxic. The pressor and anti-allergic effects of the drug are produced by oral administration. Therefore, this route may be employed in the treatment of orthostatic hypotension and allergic disorders. The comparatively larger doses required for effective oral treatment are only rarely accompanied by mild gastrointestinal symptoms. These may be avoided by administering the drug after meals.

Phenyltoloxamine Citrate

Phenyltoloxamine citrate[3] is a β-dimethylaminoethyl ether of orthobenzylphenol; as such it belongs to the group of antihistaminics exhibiting the aminoalkyl ether structure. The incidence of side effects is low; at recommended doses, soporific effects occur in less than 7% of patients.

Chlorpheniramine Maleate

Chlorpheniramine maleate[4] has good therapeutic efficacy and low incidence of side effects. It is comparable in therapeutic efficacy to other antihistaminics although administered in very low dosage.

INDICATIONS: Relief of distressing symptoms of colds and other upper respiratory infections, acute and chronic sinusitis, hay fever and other pollen allergies:

Rhinorrhea	Lacrimation
Postnasal drip	Sneezing
Nasal congestion	Itching of eyes and nose
Sinus congestion	Head stuffiness

CONTRAINDICATIONS: Sensitivity to any of the ingredients.

PRECAUTIONS: This preparation may cause drowsiness. The patient should be cautioned against engaging in operations requiring alertness such as driving an automobile, operating machinery, etc. Do not exceed the recommended dose unless directed by a physician. Individuals with high blood pressure, heart disease, diabetes mellitus, thyroid disease, glaucoma, peripheral vascular disease or prostatic hypertrophy should use only as directed by a physician.

DOSAGE: This chart represents single dosages for the products listed below. Usual dosage schedule for Naldecon Pediatric Drops, Naldecon Pediatric Syrup and Naldecon Syrup is every 3 to 4 hours, not to exceed four doses in a 24-hour period. For sustained-action Naldecon Tablets, doses should be administered on arising, in midafternoon and at bedtime.

Single Dosage for...	Pediatric Drops	Pediatric Syrup	Syrup	Tablets
3 to 6 months	1/4 ml.			
6 to 12 months	1/2 ml.	1/2 teaspoonful		
1 to 6 years	1 ml.	1 teaspoonful		
6 to 12 years		2 teaspoonfuls	1/2 teaspoonful	1/2 tablet
over 12 years			1 teaspoonful	1 tablet

Isolated Growth Hormone Deficiency and Cystic Fibrosis: A Report of Two Cases

Cystic fibrosis (CF), an inherited, chronic progressive disease, is considered a cause of failure to thrive and retarded growth. In fact, special growth curves have been constructed for patients with CF.[1,2] However, most patients with CF who survive to adulthood achieve stature in the normal range.[3] Thus, when severe growth retardation is observed in a patient with CF, it should not be attributed to CF alone and other etiologies should be sought. We have described two patients with CF who have isolated human growth hormone (HGH) deficiency.

Report of Cases.—CASE 1.—A 14-year, 8-month-old boy was found to have elevated sweat sodium and chloride concentrations at age 2 years, 9 months during an evaluation for short stature. However, at that time, he had no demonstrable respiratory or gastrointestinal disease, and other than his size and a submucosal cleft palate, physical examination showed no abnormalities. By age 5 years, however, he had had occasional symptomatic pulmonary infection and chronic changes on chest roentgenogram, and a diagnosis of CF was made. He had normal fecal fat excretion and normal pattern of amylase isozymes; and though duodenal intubation could not be accomplished, he seemed to have normal exocrine pancreatic function. His chest roentgenogram now shows coarsened peribronchial markings, early bronchiectatic changes, and hyperinflation. Sputum cultures contain *Pseudomonas aeruginosa*. At age 6 years, 9 months, deficiency of HGH was reported. Evaluations of serum calcium and phosphorus levels and liver, renal, and thyroid function have been normal. Evaluation of the pituitary-adrenal axis included normal AM and PM plasma cortisol, urinary 17-hydroxycorticosteroid and 17-ketosteroid values, and normal responses to corticotropin infusion and metyrapone tests. Within the last six months, normal pubertal changes have been observed. Pertinent data are summarized in the Table. Treatment with human growth hormone for eight years has restored normal growth velocity, and his height has paralleled the first percentile height curve.

Relevant family history includes an older brother, aged 15 years, who has CF (sweat chloride concentration, 125 mEq/L, mean of six determinations; range, 101 to 142 mEq/L). He has normal exocrine pancreatic function documented by determination of trypsin and chymotrypsin activity in his duodenal aspirate and a normal amylase isozyme pattern. Peribronchial thickening is present on chest roentgenogram and a heavy growth of *Staphylococcus aureus* is routinely found in his sputum. However, he has grown normally with a height in the 45th percentile and a weight in the 85th percentile.

CASE 2.—A 7-year, 5-month-old girl was found to have CF at four months of age and was begun on a regimen of pancreatic enzyme replacement at that time. Pancreatic insufficiency was documented by the absence of amylase, lipase, trypsin, and chymotrypsin activity in a duodenal aspirate. Her pulmonary status has been good, however; and chest roentgenogram has remained normal though sputum cultures contain *S aureus* and *P aeruginosa*. At age 4 years, 11 months, she was evaluated for short stature and found to have HGH deficiency. Serum calcium and phosphorous levels and liver, thyroid, and renal functions were normal. Assessment of the pituitary-adrenal axis included AM and PM plasma cortisol and urinary 17-hydroxycorticosteroid and 17-ketosteroid tests, the results of which were normal. Pertinent data are summarized in the Table. Human growth hormone replacement therapy was started, and she has shown an appropriate response. Three siblings, none of whom has CF, are all of normal stature.

Comment.—Although the conditions of these two patients have been well documented to be CF, a chronic disease capable of causing growth retardation, the degree of growth failure was out of proportion to the minimal degree of involvement of CF-related illness, and their heights and weights were more than 2 SDs below the mean even for patients with CF. Patient 1 has normal pancreatic function, so his growth failure cannot be explained by malabsorption. Patient 2 has pancreatic insufficiency, but she has been receiving treatment since the age of 4 months. Moreover, Sproul and Huang[1] found no correlation between pancreatic insufficiency and the degree of growth retardation in their series of patients with CF. Both patient 1 and patient 2 had normal chest roentgenograms at the time growth failure was noted, so chronic pulmonary disease cannot explain their short stature. Besides, the data of Sproul and Huang[1] indicated that severe pulmonary disease exerts its greatest influence during the adolescent growth spurt, not during early childhood when these patients were identified.

The diagnosis of HGH deficiency is also well established in our two patients. This finding probably represents a chance coexistence in these individuals. It is unlikely that the decreased plasma HGH level is secondary to some aspect of CF since both resting and stimulated plasma levels of HGH in patients with CF have been reported to be normal.[4,5] In addition there was no history of trauma or illness that could cause HGH deficiency secondarily.

Other causes of short stature that have been reported in association with CF include Down's, cri-du-chat, and Silver-Russell syndromes.[6] Of these syndromes, Silver-Russell dwarfism is the most difficult to exclude; however, plasma HGH levels have been documented to be normal in this group of patients.[6] In addition, our patients did not have the typical physical findings of these syndromes, and results of chromosomal studies were normal.

It is important for several reasons to diagnose HGH deficiency in patients with CF when it is present. Patients with CF, now living longer than ever before,[7] have many concerns about their physical habitus,[8] and correction of as many abnormalities as possible is desirable for optimal psychological adjustment. These children frequently have barrel chest, chronic cough, and greatly reduced weight for height even with optimal care; and amelioration of extremely short stature may well improve their self-image and their social function.

Also, correction or partial correction of a deficiency in the HGH level may

favorably influence the course of the pulmonary disease in CF. The lung continues to grow throughout childhood, and during the first 8 years, much of this growth is accomplished by an increase in number of mature and immature alveoli.[9] One might speculate that if this growth fails to occur, the chronic infection present in CF patients would destroy the existing lung tissue without compensation from new growth.

The importance of the influence of HGH on lung growth and function has been supported by clinical studies of patients with hypopituitarism[10] and patients with acromegaly.[10,11] Moreover, therapy with human growth hormone has been shown to increase muscle mass, and respiratory muscle endurance has been postulated as one factor that benefits the course of CF lung disease.[12] Additionally, treatment with human growth hormone has been shown to result in increased blood volume in HGH-deficient children,[13] which would be important for oxygen-carrying capability and might benefit tissue oxygenation in patients with CF. Thus, it would seem desirable from both physiologic and psychologic standpoints to locate patients with CF who have HGH deficiency and to treat them appropriately.

Hodgkin's Disease as Epitrochlear Adenopathy

The most common initial manifestations of Hodgkin's disease in children are cervical or supraclavicular adenopathy or a mediastinal mass. Axillary and inguinal lymph node involvement are much less frequent. Epitrochlear involvement is very unusual, even in the presence of generalized disease and is extremely rare as an initial and isolated manifestation of Hodgkin's disease.

Report of a Case.—A healthy 6-year-old girl, had a firm, painless, 4-cm, right epitrochlear mass. There was no history of the systemic symptoms (ie, fever, sweats, weight loss, or pruritus), local infection, animal bites or scratches, or medications. The physical examination was otherwise unremarkable.

An excisional biopsy specimen demonstrated nodular sclerosing Hodgkin's disease. Clinical assessment included complete blood cell count, sedimentation rate, liver function tests, chest tomography, gallium scan, liver-spleen scan, bipedal lymphangiography, intravenous pyelogram and bilateral posterior iliac crest bone marrow aspirates, and biopsy specimens, all of which showed no evidence of lymphoma. A staging laparotomy was not done.

The child was treated with a six-month course of multiagent chemotherapy (mechlorethamine hydrochloride, vincristine sulfate, vinblastine sulfate, procarbazine hydrochloride, and prednisone) without complication. She remains well with no evidence of recurrent disease 14 months since diagnosis.

Comment.—Epitrochlear nodal involvement in Hodgkin's disease is very unusual, even in the presence of generalized disease, but it is particularly rare as an initial manifestation. Among 300 patients treated at Yale University, New Haven, Conn, from 1958 to 1977, there were only two instances of epitrochlear involvement, both in patients with advanced disease.[1] Among 109 children with Hodgkin's disease at the Princess Margaret Hospital, Toronto, epitrochlear adenopathy was not seen.[2] Kaplan[3] noted only three instances of epitrochlear involvement among more than 300 consecutive patients of all ages. Firth[4] described a single adult with epitrochlear adenopathy as an initial and sole manifestation of Hodgkin's disease. More recently, an adult with widespread disease was described who had an epitrochlear mass.[5] In contrast to Hodgkin's disease, epitrochlear nodal involvement is more common in the non-Hodgkin's lymphomas, although still relatively infrequent.[6]

The patient described in this article received combination chemotherapy without radiation in an attempt to avoid cessation of radial and humeral epiphyseal bone growth associated with therapeutic doses of irradiation.[7,8] Whether chemotherapy alone for localized disease will have the same high cure rate as intensive radiotherapy remains to be firmly established.[9]

Seropositive Rheumatoid Arthritis in a Patient With Cystic Fibrosis

There have been sporadic reports in the literature of the coexistence of cystic fibrosis (CF) with various forms of arthritis.[1-5] We have recently observed a case of classical, seropositive, adult-type rheumatoid arthritis in a female teenager with CF.

Report of a Case.—A 16-year-old girl had her condition diagnosed as cystic fibrosis at age 3 months, with a history of steatorrhea, respiratory symptoms, and a positive sweat electrolyte test; a brother had died from the same disease. Her growth and development were higher than the 50th percentile, and she had only minor morbidity from pulmonary or gastrointestinal symptoms. Her condition was intermittently treated with prophylactic antibiotics and she received a maintenance dose of daily pancreatic extract. As rated by the Schwachman score, her clinical CF status was "excellent."

At age 14 years, she noted the insidious onset of pain and swelling in the proximal interphalangeal (PIP) joints of the right first and second fingers. She experienced similar pains and swelling that rapidly developed in additional PIP and metacarpophalangeal (MCP) joints of both hands. After six months, the joints involved included the wrists, elbows, knees, and feet; a symmetrical, progressive, additive, inflammatory polyarthritis had evolved. Associated constitutional symptoms of fatigue and morning stiffness (two hours) were also present.

Examination showed swelling and tenderness of the second, third, and fourth PIP and MCP joints bilaterally, plus tenderness of the wrists. A subcutaneous nodule was present over the left olecranon region. Severe clubbing of the fingertips was present, but this antedated the arthritis by many years and was distinguishable from the inflammatory joint disease.

Her hemoglobin level was 12.8 g/dL, the ESR (Westergren) was 33 mm/hr, and a persistently positive latex fixation test for rheumatoid factor at a titer of 1:1280 was found. Other routine blood studies were unremarkable. Urinalysis and roentgenograms of the affected joints were normal.

Initially, the patient was treated with various nonsteroidal antiinflammatory drugs, including high doses of aspirin, tolmetin sodium, etc. After several months of observation, the persistent symptoms, progressive nature of her arthritis, decreasing

hemoglobin level (to 9.1 g/dL), and increasing ESR led to start of chrysotherapy with gold sodium thiomalate. After the patient had received a total dose of 585 mg of gold in weekly divided doses of 50 mg, proteinuria was noted; this eventually reached a level of 10 g/24 hr. Gold therapy was discontinued, the proteinuria eventually resolved completely, and therapy was instituted with hydroxychloroquine sulfate, 200 mg twice daily. After four months of therapy with this medication, a substantial remission has ensued, characterized by disappearance of objective joint inflammation, subsidence of morning stiffness to less than 20 minutes, and an increase in hemoglobin level to 11.9 g/dL. The rheumatoid factor titer, ESR, and pulmonary disease were unchanged.

Comment.—Several causes of joint pain in patients with CF may be encountered. Hypertrophic pulmonary osteoarthropathy with joint pains and appropriate radiologic changes is a well-known finding in many cases of CF.[1] Newman and Ansell[2] recently reported a study of five patients with CF who had transient arthritis involving the large joints, which resolved spontaneously in one to ten days. These patients also had an erythematous rash contiguous with the affected joints, and they were all seronegative for rheumatoid factor. Our patient had a seropositive, progressive, sustained arthritis unassociated with any rash and does not fit this category.

Mathieu et al[3] reviewed several patients with "rheumatoid arthritis" and pulmonary infection. Five patients in their series had positive rheumatoid factor tests, but two of these had bronchiectasis (rather than CF) as their primary pulmonary problem. Of the three seropositive patients with CF, two had pauciarticular arthritis associated with low titers of rheumatoid factor, and neither patient would seem to meet currently accepted criteria for classification of rheumatoid arthritis. One of their patients, a 19-year-old woman, had a strongly positive rheumatoid factor test associated with pain, swelling, and stiffness of numerous joints, and this patient's condition would seem to have also been a case of seropositive rheumatoid arthritis with CF. The current case, however, seems to be the first to have had nodules in addition to the other classic manifestations of adult-type rheumatoid arthritis.

A few minor causes of joint pain in patients with CF have also been reported. A 6½-year-old patient had a seronegative polyarthritis followed two years later by the manifestations of Crohn's disease.[4] (In our CF clinic, we are currently following up a 26-year-old woman with biopsy specimen-proved Crohn's disease who has never had arthritis.) Some patients with CF have hyperuricemia that can be secondary to administration of large doses of supplemental pancreatic enzymes.[5] Patients with pancreatic disease are also subject to certain forms of arthritis.[6]

The development of a positive test for rheumatoid factor in chronic inflammatory states is well documented.[7] However, patients with CF, despite the fact that they have multiple pulmonary infections, do not have a higher incidence of rheumatoid factor than normal populations.[8] In the present case, the appearance of the rheumatoid factor in the serum was coincident with the development of the arthritis and was probably not a manifestation of chronic antigenic stimulation from an infectious source. It remains to be seen if the coexistence of the two disorders in this patient will enhance the risk of pulmonary infection in later years.

Since there is an enlarging population of patients of increasing longevity who have CF, many such patients can be expected to get the diseases of adulthood. We have reported a case of classical, seropositive rheumatoid arthritis of the adult type in a 16-year-old girl with CF. This may have been fortuitous, but it remains to be seen whether patients with CF may indeed have an increased incidence of this or other connective tissue disorders as they grow older.

Congenital Miliary Tuberculosis Proved by Open Lung Biopsy Specimen and Successfully Treated

Congenital tuberculosis is a rare disease with a high mortality.[1-7] Fewer than 200 cases have been reported in the world literature; less than 100 in the United States.[2] The incidence is not known. A patient who was successfully treated is described.

Report of a Case.—The patient was a 3-kg product of a full-term pregnancy. During the first trimester, the mother suffered an illness consisting of fever, cough, and right-sided chest pain. Her condition was diagnosed as being pleurisy and bronchitis. The remainder of the pregnancy and the immediate postnatal period were uneventful. At 3 weeks of age, the baby was transferred to the Children's Hospital from an outlying hospital where he had been treated for five days for fever, cough, and anorexia.

The baby was lethargic. The rectal temperature was 38.5 °C. The respiratory rate was 40/min, the heart rate was 146 beats per minute, and the blood pressure was 60/40 mm Hg. The lungs were clear to auscultation. The liver was palpable 4 cm below the right costal margin. The spleen was felt 1 cm below the left costal margin. A WBC count was 18,200/cu mm, with 46% band forms, 44% polymorphonuclear leukocytes, and 8% lymphocytes. The hematocrit reading was 45. A platelet count was 144,000/cu mm. Urinalysis, electrolyte, blood urea nitrogen, and serum glucose test results were normal. The CSF was normal on two occasions. The lactate level of the second CSF was normal. A chest roentgenogram showed an extensive miliary infiltrate (Fig 1).

Viral cultures and tests for syphilis, toxoplasmosis, and rubella were negative. Serum immunoglobulin test, bone marrow aspirate, skeletal roentgenograms, and ophthalmoscopy showed no abnormalities. An abdominal roentgenogram showed moderate hepatosplenomegaly. An initial

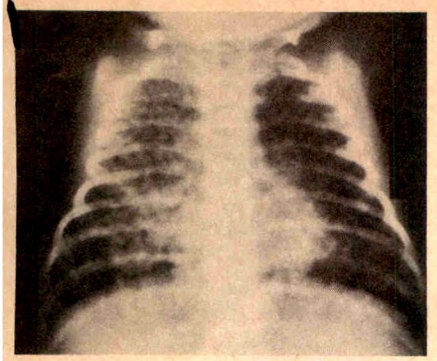

Fig 1.—Film of chest at 3 weeks of age.

Fig 2.—Lung biopsy specimen showing hypercellularity, subpleural alveolar obliteration, and proliferation of large histiocytic cells.

intradermal skin test using intermediate strength (5 TU) of purified protein derivative of tuberculin was negative at 48 hours.

A chest roentgenogram of the patient's mother showed pleural thickening on the right. At 48 hours, her tuberculin skin test was read as 15 mm of induration. The patient's father and brother had normal chest roentgenograms and negative skin tests. The mother was given isoniazid, 300 mg daily, by her local health department.

The day after admission, the baby was begun on a regimen of isoniazid, 15 mg/kg/day; streptomycin sulfate, 35 mg/kg/day; and rifampin, 15 mg/kg/day. An open-lung biopsy specimen at 5 weeks of age confirmed the diagnosis of miliary tuberculosis. Light microscopy showed areas of large histiocytes and lymphocytes (Fig 2). *Mycobacterium tuberculosis hominis*, niacin-positive, sensitive to isoniazid, grew from culture.

The patient's condition improved steadily during the remainder of his hospitalization, and he was discharged at 2 months of age. He has been followed up in the chest clinic at the Children's Hospital where his psychomotor development has been normal. A follow-up PPD at 6 months of age was positive (10-mm induration).

At 8 months of age, the patient's height, weight, and head circumference are at the 50th percentile. His physical examination showed no abnormalities. His chest roentgenogram shows substantial improvement. No calcifications have been identified to date in either the lungs or the liver. Results of liver function tests have remained normal.

Comment.—Congenital tuberculosis may be defined as an infection of the child with *M tuberculosis* contracted from the mother during intrauterine life. Avenues of infection include aspiration or ingestion of infected amniotic fluid and transplacental hematogenous spread through the umbilical vein to the fetal liver.[8] In 1935, Bietzke[9] proposed the criteria necessary to insure the congenital nature of the disease. These are as follows: (1) The diagnosis of tuberculosis must be proved in mother and child. (2) The infant must have a primary tuberculous complex in the liver. (This usually is demonstrable only if calcification appears roentgenographically.) (3) The lesions must be present in the first few weeks of life, or if points 2 and 3 are not fulfilled, then extrauterine infection must be excluded.

In the case reported, the probable route of infection was hematogenous, with infection of the infant via the umbilical vein. The age of onset (3 weeks), histologic findings of the lung, and the history of pleural effusion during the first trimester are all compatible with this route of infection. Furthermore, there were no other cases of tuberculosis found in the family. Unfortunately, no placental tissue was available.

Few survivors of congenital tuberculosis have been recorded.[10-11] Early and aggressive diagnostic and therapeutic measures are mandatory to improve survival. The disease must be suspected in infants with otherwise unexplained pulmonary disease, especially in those born to tuberculous mothers. Placentas from those pregnancies should, if possible, be examined histologically. Infants born to mothers with positive skin tests should receive extremely close observation and follow-up. When active tuberculosis is found during pregnancy, treatment may prevent transmission to the fetus.

Amantadine for Severe Influenza A Pneumonia in Infancy

Influenza A virus may cause severe illness in infancy.[1,2] Amantadine hydrochloride is effective as a prophylactic agent[3,4] and is free of serious side effects[5] when administered to older children. Although therapeutic field trials with amantadine have included children,[6] we are unaware of any attempts to treat serious illness caused by influenza A in childhood, nor are there dosage recommendations for children under 1 year of age.

Report of a Case.—A 5-month-old girl was admitted to Colorado General Hospital on Dec 21, 1977, with fever, cough, and tachypnea. Physical examination revealed otitis media and a seborrheic skin rash. A chest roentgenogram revealed diffuse interstitial infiltrates. In ambient oxygen, the Pao_2 was 38 mm Hg; the WBC count was 13,300/cu mm. She was treated with forced inspiratory oxygen (FIO_2) of 40% and received broad-spectrum antibiotics for presumed bacterial pneumonia and sepsis until cultures of blood, spinal fluid, and urine proved to be sterile. Increasing respiratory distress and worsening interstitial infiltrates led to the performance of a percutaneous needle aspiration of the left lung on Dec 29, 1977. Cultures of the aspirate fluid and the upper respiratory tract taken six days earlier grew influenza A virus (A/Vic/3/75). Methenamine silver-stained specimens of the aspirate fluid

revealed *Pneumocystis carinii*. The infant was treated with trimethoprim-sulfamethoxazole (20 mg/kg/day of trimethoprim) and, because of the gravity of her illness, with amantadine hydrochloride (2.5 mg/kg/12 hours), after informed consent was obtained. Both compounds were administered by nasogastric tube. She was placed on assisted ventilation, ultimately requiring an FIO_2 of 100% and end-expiratory pressures of 15 cm of H_2O. Abnormalities of hepatic, hemostatic, and neurologic function appeared; renal function remained normal. Because of the unusual combination of infectious agents, an immunological evaluation was performed, yielding a diagnosis of the syndrome of cellular immunodeficiency with immunoglobins[7] (M. Fishaut, MD, D. Tubergen, MD, K. McIntosh, MD, unpublished observations, 1978). She died on Jan 6, 1978. Microscopic examination of the lungs revealed hemorrhage and gross consolidation. Silver-stained specimens were positive for *P carinii*.

The needle aspiration fluid, respiratory secretions, and tissue specimens obtained at postmortem examination were inoculated into primary rhesus monkey kidney cell monolayers that were assessed for influenza virus by patterns of hemadsorption and cytopathic effect. Isolates were subtyped by hemagglutination inhibition.[8] Specimens were also titrated for infectivity in rhesus monkey kidney. Virus was cultured for 15 days with peak titers of $10^{5.5}$ tissue culture infective dose ($TCID_{50}$)/0.1 mL of secretion. All isolates were influenza A/Vic/3/75. Of the tissues from which specimens were obtained, virus was recovered only from the lung.

Amantadine concentrations, measured by a gas chromatographic electron capture technique, were determined from pooled sera, timed sera, a random urine specimen, and several tissue specimens obtained 4½ hours after the final dose. The concentrations of amantadine are summarized in the Table. Serum concentrations ranged from 0.80 μg/mL to 1.64 μg/mL. Higher concentrations were found in urine and in several tissues, particularly lung (21.40 μg/mL).

Amantadine Hydrochloride Concentrations in Serum, Urine, and Tissue Specimens

Date	Specimen	Amantadine Concentration, μg/mL
Dec 31, 1977	Serum	0.88
Jan 1, 1978	Serum	0.82
Jan 2, 1978	Serum	0.80
Jan 6, 1978	Serum	1.64 (predose)
Jan 6, 1978	Serum	1.54 (60 min postdose)
Jan 6, 1978	Urine	17.30
Jan 6, 1978	Lung	21.40
Jan 6, 1978	Liver	11.70
Jan 6, 1978	Kidney	2.40
Jan 6, 1978	Brain	1.70
Jan 6, 1978	Bone marrow	0.36

Comment.—Amantadine hydrochloride has been administered to an infant in an attempt to limit the excretion of rubella virus,[9] but the youngest child reported to have received amantadine for influenza A prophylaxis was 15 months old.[5] Little is known about the behavior of this compound in the very young. In young adults, amantadine administered as a single 4 mg/kg dose has been found to have a half-life of nine to 15 hours, with a peak plasma concentration of 0.5 μg/mL, and to be excreted unchanged in the urine.[9] Older patients chronically receiving 200 to 300 mg/day of amantadine achieve serum concentrations of up to 1.12 μg/mL with a half-life of 30 hours,[10,11] while a group of children and young adults with cystic fibrosis receiving 6 mg/kg/day for one month achieved mean blood concentrations of 0.6 μg/mL.[5]

We chose 5 mg/kg/day divided into two doses for our patient in whom normal renal function was maintained throughout the illness. The serum concentrations were comparable to those in older children and adults: despite the infant's overall ill health, the compound was well absorbed from the gastrointestinal tract. The terminal serum concentrations were slightly elevated but well below those at which toxicity has been observed.[12] Thus our dosage schedule, in the presence of normal renal function, seems a reasonable one for infants.

Tissue concentrations of amantadine have been reported previously only in rodents.[13] We observed an approximately fourteenfold concentration of amantadine in lung over serum concentration after seven days of therapy to a level that significantly inhibits the replication of many influenza A viruses, including A/Vic/3/75, in tissue culture.[14] In vivo virus replication was not inhibited, in spite of the high concentration of drug in the lung. However, this child did have underlying immunodeficiency, as well as infection with *P carinii*. Amantadine-resistant strains of influenza A have been described,[15] but we were unable to test our patient's isolate.

Although amantadine did not alter the course of this child's infection, observations have been made of positive effects in influenza A infection.[16] These observations, coupled with our observation of high drug concentrations in serum and lung despite overwhelming illness, suggest that amantadine might be useful in the treatment of severe influenza A infection in children.

Lidocaine Ingestion

Lidocaine hydrochloride is a useful local anesthetic and antiarrhythmic agent. Serious adverse systemic reactions to lidocaine are reported to be uncommon with parenteral dosage forms and extremely rare with the topical dosage form. We are reporting a case of accidental lidocaine (Xylocaine 2% viscous) hydrochloride ingestion resulting in seizures and respiratory arrest. We have found no other reported case of lidocaine 2% viscous ingestion in the literature.

Report of a Case.—A 22-month-old female infant, weighing 10 kg, ingested 20 to 25 mL of lidocaine 2% viscous, which had been prescribed because of stomatitis. She began convulsing at home and convulsed continually while her mother was bringing her to the emergency room. On arrival at the hospital, she was cyanotic and mottled in appearance, was convulsing intermittently, and had no respirations. She was observed to have a large quantity of mucus in her hypopharynx, and it was feared that she had aspirated stomach contents. Her heart rate was 160 beats per minute, and her systolic blood pressure was 160 to 180 mm Hg. A clear diastolic pressure could not be determined.

Blood analysis demonstrated a pH of 6.96, a P_{CO_2} of 106, a P_{O_2} of 85, a bicarbonate-ion concentration of HCO_3 of 23 mM/L, with a base excess of −12. This sample was taken after she had been intubated and was being ventilated with oxygen. Her WBC count was 13,200/cu mm, with 16% polymorphonuclear cells and 84% lymphocytes. Results of urinalysis were normal.

The patient was successfully resuscitated, and her seizures were controlled with intravenous (IV) diazepam. Her respiratory status was stable 1½ hours after arrival at the hospital, and she was transferred to the intensive care unit. During the next 12 hours, she was mildly febrile, with a temperature of 39 °C. Hemodynamics remained stable, and she demonstrated no arrhythmias. Twenty-four hours after admission, she was afebrile and alert, and she was transferred to the general pediatric ward. She was discharged 48 hours after admission.

Follow-up.—The patient, now 3 years old, seems to have suffered no developmental sequelae as a result of this incident.

Comment.—Lidocaine is well absorbed through the mucous membranes and from the gastrointestinal tract. Only about 35% of an oral dose reaches the systemic circulation because lidocaine undergoes extensive hepatic metabolism.[1] Some investigators have indicated that the metabolite is pharmacologically active and may in fact be partly responsible for some of the toxic effects.[1] Lidocaine rapidly distributes into tissues and is then eliminated from the serum at a relatively slower rate, with a serum half-life of one to 1½ hours.[2] After oral administration, peak serum concentrations are seen in 30 to 60 minutes.[1] There is a correlation between serum concentration and adverse reactions.[3] The CNS adverse reactions usually predominate, but cardiovascular adverse reactions may also be seen when high serum concentrations are achieved. Symptoms of lidocaine toxicity include drowsiness, dizziness, paresthesias, muscle twitching, dysarthrias, blurred vision, vomiting, hypotension, bradycardia, respiratory arrest, convulsions, and death.[1,3-7] Our patient interestingly had both hypertension and tachycardia. Lidocaine depresses the cough reflex.[8] Cohen and Levinsky,[9] in 1976, reported an adult case of aspiration secondary to lidocaine viscous therapy. The prescribed dose in that case was only 5 mL before meals.

Our patient ingested approximately 25 mL of a 2% solution or 50 mg/kg of lidocaine. Assuming 35% reaches the systemic circulation after oral ingestion, 17.5 mg/kg reached the systemic circulation in this patient. The recommended IV antiarrhythmic dose is 1 to 5 mg/kg by IV bolus to be followed by a 10 to 50 μg/kg/min continuous infusion to maintain therapeutic serum concentrations.[10] Thus, approximately 3½ times the maximum recommended IV loading dose reached the systemic circulation after oral ingestion in this patient.

Conclusion.—Physicians prescribing lidocaine 2% viscous should know that 25 mL may result in serious adverse reactions, as exemplified in our patient. Lidocaine 2% viscous now has a safety cap, but old stock lacking a safety cap may still be available in some wholesale houses, pharmacies, and scattered medicine cabinets throughout the country.

Based on absorption data and the kinetics of lidocaine, one can predict that toxicity will be seen soon after ingestion and will peak in 30 to 60 minutes. Improvement should be seen two to three hours after ingestion, and the adverse symptoms should disappear by 12 to 24 hours in patients with normal renal and hepatic function. Therapy should include (1) discontinuation of further exposure to lidocaine; (2) maintenance of adequate respiratory status; and (3) treatment of seizures, if present, with anticonvulsants. Lidocaine 2% viscous toxicity is not common, but careful supportive treatment must be started promptly. With supportive treatment, adverse symptoms subside soon after ingestion.

Ilosone® (erythromycin estolate)

WARNING

Hepatic dysfunction with or without jaundice has occurred, chiefly in adults, in association with erythromycin estolate administration. It may be accompanied by malaise, nausea, vomiting, abdominal colic, and fever. In some instances, severe abdominal pain may simulate an abdominal surgical emergency.

If the above findings occur, discontinue Ilosone promptly.

Ilosone is contraindicated for patients with a known history of sensitivity to this drug and for those with preexisting liver disease.

Indications: *Streptococcus pyogenes* (Group A Beta-Hemolytic) – Upper and lower respiratory tract, skin, and soft-tissue infections of mild to moderate severity.

Injectable penicillin G benzathine is considered by the American Heart Association to be the drug of choice in the treatment and prevention of streptococcal pharyngitis and in long-term prophylaxis of rheumatic fever.

When oral medication is preferred for treating the above-mentioned conditions, penicillin G or V or erythromycin is the alternate drug of choice.

The importance of the patient's strict adherence to the prescribed dosage regimen must be stressed when oral medication is given. A therapeutic dose should be administered for at least ten days.

Alpha-Hemolytic Streptococci (Viridans Group) – Short-term prophylaxis against bacterial endocarditis prior to dental or other operative procedures in patients with a history of rheumatic fever or congenital heart disease who are hypersensitive to penicillin. (Erythromycin is not suitable prior to genitourinary surgery when the organisms likely to lead to bacteremia are gram-negative bacilli or belong to the enterococcus group of streptococci.)

Staphylococcus aureus – Acute infections of skin and soft tissue which are mild to moderately severe. Resistance may develop during treatment.

S. (Diplococcus) pneumoniae – Infections of the upper respiratory tract (e.g., otitis media, pharyngitis) and lower respiratory tract (e.g., pneumonia) of mild to moderate severity.

Mycoplasma pneumoniae (Eaton Agent, PPLO) – Respiratory tract infections due to this organism.

Haemophilus influenzae – May be used concomitantly with adequate doses of sulfonamides for upper respiratory tract infections of mild to moderate severity. Not all strains of this organism are susceptible at the erythromycin concentrations ordinarily achieved.

Treponema pallidum – As an alternate treatment in penicillin-allergic patients. In primary syphilis, spinal-fluid examinations should be done before treatment and as part of follow-up after therapy.

Corynebacterium diphtheriae – As an adjunct to antitoxin, to prevent establishment of carriers, and to eradicate the organism in carriers.

C. minutissimum – In the treatment of erythrasma.

Entamoeba histolytica – For intestinal amebiasis only. Extraenteric amebiasis requires treatment with other agents.

Listeria monocytogenes – Infections due to this organism.

Legionnaires' Disease – Although no controlled clinical efficacy studies have been conducted, in vitro and limited preliminary clinical data suggest that erythromycin may be effective in treating Legionnaires' disease.

Contraindication: Known hypersensitivity to this antibiotic.

Warnings: (*See* Warning box above.) The administration of erythromycin estolate has been associated with the infrequent occurrence of cholestatic hepatitis. Laboratory findings have been characterized by abnormal hepatic function test values, peripheral eosinophilia, and leukocytosis. Symptoms may include malaise, nausea, vomiting, abdominal cramps, and fever. Jaundice may or may not be present. In some instances, severe abdominal pain may simulate the pain of biliary colic, pancreatitis, perforated ulcer, or an acute abdominal surgical problem. In other instances, clinical symptoms and results of liver function tests have resembled findings in extrahepatic obstructive jaundice.

Initial symptoms have developed in some cases after a few days of treatment but generally have followed one or two weeks of continuous therapy. Symptoms reappear promptly, usually within 48 hours after the drug is readministered to sensitive patients. The syndrome seems to result from a form of sensitization, occurs chiefly in adults, and has been reversible when medication is discontinued.

Usage in Pregnancy – Safety of this drug for use during pregnancy has not been established.

Precautions: Caution should be exercised in administering the antibiotic to patients with impaired hepatic function.

Recent studies of erythromycin reveal that its use in patients receiving high doses of theophylline may be associated with an increase in serum theophylline levels and potential theophylline toxicity. In such a case, the dose of theophylline should be reduced while the patient is receiving concomitant erythromycin therapy.

Surgical procedures should be performed when indicated.

Adverse Reactions: The most frequent side effects are gastrointestinal (e.g., abdominal cramping and discomfort) and are dose related. Nausea, vomiting, and diarrhea occur infrequently with usual oral doses.

During prolonged or repeated therapy, overgrowth of nonsusceptible bacteria or fungi is possible. If such infections arise, the drug should be discontinued and appropriate therapy instituted.

Mild allergic reactions, such as urticaria and other skin rashes, have occurred. Serious allergic reactions, including anaphylaxis, have been reported. [013079]

Letters to the Editor

Pediatrics and Record-keeping

Sir.—I appreciated the careful study of the use of ambulatory medical records reported by Margolis and Porter (JOURNAL 132:1115-1116, 1978). Although their observations are clearly presented, I had thought that the responsibility of the pediatrician at any acute ambulatory visit would involve review of the patient's total health status. Identification of chronic health problems and their current condition, review of health problems identified at the last visit or by telephone during the interval, determination of immunization status and currentness of preventive health care, inquiry regarding additional health problems, and identification of the time of the next appropriate ambulatory visit would be included. Furthermore, recurrent health problems are so much the rule in pediatrics that, except in the setting of the occasional emergency room visit, it would seem to me that the time expended in identifying the case with a nonrecurrent problem would outweigh the saving achieved by not pulling the record. Even in the apparently nonrecurrent problem, in my own office, where charts are regularly reviewed both at office visits and when emergency room copies are received, previous similar pathology or contributory problems in areas such as allergic, developmental, social, and emotional disturbance are frequently found.

I would hope that the report by Drs Margolis and Porter would not discourage those seeking to eliminate fragmentation in ambulatory pediatric care. Particularly in these days, when young families' roots are not always strong and when medical science is increasingly complex and changing, young patients and their parents need the assurance provided by a medical home, so medical care may be comprehensive and well coordinated.

DAVID SPARLING, MD
6343 Motor Ave SW
Tacoma, WA 98499

In Reply.—Dr Sparling is misinterpreting our report if he believes that we are trying to detract from the importance of comprehensive care. His reservations may be related to the differences in the practice setting: the prepaid health insurance system that covers more than 90% of all the patients in our study results in a high number of visits per annum, compared with the number of visits in a fee-for-service operation. If most of our patients see the pediatrician on an average of six times per year (as well as separate "well baby" visits to a preventive-medicine nurse four to five times in a year), then review of the patient's total health status at each visit is simply not necessary. So, we could certainly add that our conclusions are conditional on periodic comprehensive appraisal of the patient's problem list, at separate visits.

If our differences of opinion are not related to practice setting, then we do not agree that every acute visit demands a comprehensive review. In our opinion, no primary care setting that provides acute care can afford to give comprehensive care at the same time.

Recurrent Abdominal Pain

Sir.—What causes recurrent abdominal pain in children? And what should pediatricians do about it?

If a comprehensive battery of the usual studies (such as a complete blood cell count, urinalysis, ESR, examination of the stool for ova and parasites, and gastrointestinal (GI) roentgenograms show no abnormalities, what then? Should the patient be referred for psychiatric counseling because nothing "organic" has been found? Or should he undergo even more extensive testing and study, including EEG, rectal biopsy, sigmoidoscopic examination, or exploratory laparotomy?

Or could there be a simpler answer for a child's problem? A simpler diagnostic test, such as the elimination diet?

In the past 17 months, two separate articles with the identical title, "Recurrent Abdominal Pain," have appeared in the JOURNAL (131:1340-1344, 1977 and 133:486-489, 1979). One study consisted of a review of the management of 19 patients, while the other was a long-term follow-up study of 161 children. In both of these reports, the authors said, in effect, "When the usual studies show no organic cause for a child's recurrent abdominal pain, we approach the problem from the emotional point of view." Moreover, the references cited in each of these reports included publications that presented an identical point of view. Yet they ignored the possibility that recurrent abdominal pain may be caused by adverse or allergic reactions to food, especially cow's milk.

Through the years, a number of physicians have pointed out that recurrent abdominal pain can be a manifestation of hidden, masked, nonreaginic, or delayed-onset food allergy and a cardinal symptom of "food toxemia" or the allergic tension-fatigue syndrome.[1-6] Moreover, a recent report indicates that lactose intolerance may also play an important role in causing recurrent abdominal pain even though other GI symptoms are absent.[7]

To determine whether or not a child's recurrent abdominal pain is caused by an adverse or allergic reaction to one or more foods requires the following: (1) awareness that such food-induced reactions occur; (2) recognition of the symptoms that characteristically accompany food-induced abdominal pain, including pallor, infraorbital circles, nasal stuffiness, headache, limb pain, fatigue, and mental and emotional symptoms; and (3) carrying out, by the patient, of a carefully planned elimination diet lasting from seven to 21 days, followed by challenges to determine the food offenders. Although I do not claim to understand all of the mechanisms involved in such reactions, in my experience during the past 23 years of general pediatric and allergy practice, adverse or allergic reactions to common foods have been the most frequent cause of chronic complaints among my patients.

Physicians and other professionals who would like a copy of the elimina-

tion diet I use may obtain it by sending me a stamped, self-addressed envelope.

6. Crook WG: Food allergy: The great masquerader. *Pediatr Clin North Am* 22:227-238, 1975.

7. Barr RG, Levine, MD, Watkins, JB: Recurrent abdominal pain of children due to lactose intolerance. *N Engl J Med* 300:1449-1452, 1979.

In Reply.—In 26 years of practice during which I have seen many children with abdominal pain and the so-called tension-fatigue syndrome (headaches, infraorbital circles, limb pain, and so forth), I have yet to substantiate "milk allergy" as the basis for the complaints. Although a large body of empirical information repeatedly emphasizes the importance of milk allergy, I believe that we in the medical profession should take a firm stand against such empiricism by demanding carefully *controlled* studies of the problem.

Recently at our institution, Charles D. May, MD, presented his views about food allergy. He stated, "Proof that a food causes an adverse reaction and that the manifestations are not psychologic in origin is obtained with a food challenge."[1] Only patients with symptoms suggesting an anaphylactic reaction need not undergo a double-blind challenge. In cases of suspected food allergy, May demands that the offending food be placed in a capsule and that the patient be given either a placebo or the possibly allergenic food in this capsule. Neither the patient nor the observer should know whether the allegedly offending food is given. If the reaction is positive, this verifies a relationship between ingestion and an ill effect, but it does not provide information about the presence or absence of an immune mechanism or the involvement of the immune mechanism. If an IgE-mediated adverse reaction is suspected, properly performed skin testing[2] and the radioallergosorbent test may be useful ancillary diagnostic studies.[3-5]

It would be foolish to state that there is no such thing as food allergy; indeed, there are excellent and well-proved examples. However, the assumption that the use of milk is associated with widespread food allergy is a faddist belief, which is being adopted by an increasing number of physicians. Because of such beliefs, the use of soy formulas has increased. Possibly, the fear of milk allergy has created anxiety rather than promoting useful therapeutic management. If Dr Crook can demonstrate by carefully controlled studies that milk allergy, indeed, causes abdominal pain, I certainly would be grateful.

In our long-term follow-up study, we did not find a single patient who proved to have milk allergy, and our approach to managing the school phobia in these patients resulted in a substantial cure rate. We realize that this approach is also empirical, but thus far, no one has found a method of designing controlled studies for psychosomatic disorders. We are aware of the study in Boston by Barr et al (Dr Crook's reference 7), but we are concerned about the absence of controls in their study. Because psychosomatic abdominal pain is such a frequent condition (namely, one in nine schoolchildren have it), it would not be unusual to find lactose intolerance in patients who have true school phobia. The latter needs to be studied further; routine exclusion of lactose intolerance in patients with recurrent abdominal pain may be necessary. Never did we suggest studies or procedures such as electroencephalography, rectal biopsy, or sigmoidoscopy as part of a routine examination for patients with recurrent abdominal pain, and we emphatically oppose the use of exploratory laparotomy.

60 YEARS AGO IN THE AJDC

An Improved Needle for Sinus Therapy

Used extensively in the Babies' Hospital for "intravenous administration of arsphenamin, physiologic sodium chloride solution, glucose and sodium bicarbonate solution as well as for withdrawal of blood for diagnostic purposes," the author invented the needle set-up pictured. It represents an improved method of puncturing the sagittal sinus, was considered safer than one previously employed which entered at a 90 degree angle and could readily puncture the opposite wall of the sinus or cerebral cortex.

The sagittal sinus is entered immediately forward of the posterior angle of the anterior fontanelle. For young infants 4 to 6 millimeters of needle is used; 5 to 8 millimeters for older ones.—Alton Goldbloom, MD, Babies' Hospital, New York (19:229, March 1920).

Brief Summary

E.E.S.®

(ERYTHROMYCIN ETHYLSUCCINATE)

Indications: *Streptococcus pyogenes* (Group A beta hemolytic streptococcus)—Upper and lower respiratory tract infections, skin, and soft tissue infections of mild to moderate severity, where oral medication is preferred. Therapy should be continued for 10 days.

Alpha-hemolytic streptococci (viridans group)—Short-term prophylaxis of bacterial endocarditis prior to dental or other operative procedures in patients with a history of rheumatic fever or congenital heart disease who are hypersensitive to penicillin.

S. aureus—Acute infections of skin and soft tissue of mild to moderate severity. Resistant organisms may emerge during treatment.

S. pneumoniae (D. pneumoniae)—Upper and lower respiratory tract infections of mild to moderate degree.

M. pneumoniae—For respiratory infections due to this organism.

Hemophilus influenzae: For upper respiratory tract infections of mild to moderate severity when used concomitantly with adequate doses of sulfonamides. Not all strains of this organism are susceptible at the erythromycin concentrations ordinarily achieved (see appropriate sulfonamide labeling for prescribing information).

Treponema pallidum—As an alternate treatment in patients allergic to penicillin.

C. diphtheriae and C. minutissimum—As an adjunct to antitoxin. In the treatment of erythrasma.

Entamoeba histolytica—In the treatment of intestinal amebiasis.

L. monocytogenes—Infections due to this organism.

Legionnaires' Disease—Although no controlled clinical efficacy studies have been conducted, *in vitro* and limited preliminary clinical data suggest that erythromycin may be effective in treating Legionnaires' Disease.

Establish susceptibility of pathogens to erythromycin, particularly when *S. aureus* is isolated.

Contraindications: Known hypersensitivity to erythromycin.

Warnings: Safety for use in pregnancy has not been established.

Precautions: Exercise caution in administering to patients with impaired hepatic function. There have been reports of hepatic dysfunction, with or without jaundice, occurring in patients receiving oral erythromycin products. Recent data from studies of erythromycin reveal that its use in patients who are receiving high doses of theophylline may be associated with an increase of serum theophylline levels and potential theophylline toxicity. In cases of theophylline toxicity and/or elevated serum theophylline levels the dose of theophylline should be reduced while the patient is receiving concomitant erythromycin therapy. Surgical procedures should be performed when indicated.

Adverse Reactions: Dose-related abdominal cramping and discomfort. Nausea, vomiting, and diarrhea infrequently occur. During prolonged or repeated therapy, there is a possibility of overgrowth of nonsusceptible bacteria or fungi. Mild allergic reactions such as urticaria and other skin rashes may occur. Serious allergic reactions, including anaphylaxis, have been reported.

How to Write and Publish a Scientific Paper, by Robert A. Day, 160 pp, $15 (hardcover), $8.95 (paperback), Philadelphia, ISI Press Inc, 1979.

In exchange for freedom of inquiry, scientists are obliged to explain their work.

CARL SAGAN

It is clever, of course, to be clever
And good, of course, to be good
But when you're so frightfully clever
As seldom to be understood
It's sad, though if anything sadder
Not to be quite as good as you should.

LEWIS CARROLL

As you record your experiments, do you compose your manunscript as a murder mystery waiting until the last paragraph of the discussion section for the denouement? Do you clutch to your breast the fine details of your experimental technic so your colleagues cannot reproduce them? Do you write in the text each and every detail of the tables in the event that they are not read properly? Do you imply the fact that the results of your study on five rats will be a turning point in your field or, conversely, are you afraid to discuss the implications of your study?

Robert Day offers some very practical suggestions for dealing with these problems. In a witty and direct style he describes how to write clearly each section of a manuscript—Introduction, Materials and Methods, Results, and Discussion—and how to prepare readable tables and figures. Selection of a journal appropriate to your type of study and the most appropriate methods of dealing with editors, and if your lucky, printers is reviewed.

This book is only 160 pages in length consequently, the chapters on proper style, syntax, spelling, and avoiding jargon are unfortunately limited for brevity's sake.

Now that you have read this far, you should have detected at least ten common errors in my style, spelling, punctuation, and use of jargon. If these errors are not obvious to you, do not waste any more time before you pick up this brief, delightful, and informative effort to improve the art of scientific communication. While your interest in these matters is piqued, please read on in a recently updated classic by Strunk and White[1] and consult frequently Bernstein's entertaining and enlightening volume on "The Careful Writer".[2] If you're the stubborn type and think such views are shared by only a few, read further with Flesch[3] and the Stylebook.[4]

Haemorrhage, Ischaemia and the Perinatal Brain, by Karen E. Pape and J. S. Wigglesworth, 196 pp, $25, London, Spastics International Medical Publications, 1979.

Interest in the cerebral vasculature of the neonate has steadily increased as the success of modern perinatal care decreases mortality and morbidity for infants of all birth weights. Physicians have increasingly realized that many newborns die of intracranial vascular accidents and that the morbidity of those who survive is frequently related to vascular lesions producing neurological damage. Indeed, nearly one half of infants born prior to 32 weeks' gestation have some degree of intracranial hemorrhage depicted on computerized axial tomographic scans. In this book, the authors focus on the two major mechanisms by which the brain is most frequently damaged in the newborn, hemorrhage and ischemia. These mechanisms are examined from multiple aspects in an effort to prepare the reader for what Dr G Avery calls in the introduction "... a new era in the intensive care of the brain of the small premature."

The authors are both qualified specialists, who bring differing perspectives to this complex subject. Dr Pape is a neonatologist with experience in neurodevelopment, and Dr Wigglesworth is a pathologist. Both have worked in this field for many years and have published original work on neurological lesions in the newborn. Their combined expertise has produced a text that interrelates many facets of neonatal cerebral vasculature and provides the reader with multiple perspectives on this fascinating subject.

The book begins with a look at the economic importance of intracranial hemorrhage and ischemia. In the introductory chapter, the authors state these processes "now account for a high proportion of all neonatal mortality and permanent neurological handicap." After this, chapter 2 examines the cerebral blood supply to the developing brain. Here the authors discuss their own detailed anatomical studies of cerebral vasculature in the developing brain between 24 and 40 weeks' gestation. They emphasize the vascularity of the germinal matrix and its extensive capillary bed during the 24- to 28-weeks' gestational period, along with the striking proliferation of cortical vascularity after 32 weeks' gestation. This original work is excellent, is illustrated by superb photographs, and lays a solid foundation for the discussions that follow. Other chapters then examine the physiology of cerebral circulation, classification of cranial hemorrhage, hemorrhagic lesions, and other aspects of the problem as they relate to the newborn. The chapters are well researched, clearly written, and contain excellent references and illustrations.

The authors' working model of how cerebral vasculature is controlled includes a proposed mechanism for ischemic lesions. Throughout the text, there is scattered discussion of ischemia, but the emphasis is mainly on hemorrhagic lesions. The authors have successfully pulled together a variety of studies and provide the

reader with a broad background for understanding the anatomical and physiological basis for CNS damage in the neonate. They not only provide new material of their own, but they also prepare the reader for a better understanding of the studies that are now appearing in journals. The book can be highly recommended to anyone dealing with newborns, especially those who care for preterm infants.

Pediatric Burns, edited by Wm. Carl Biley, 150 pp, Chicago, Year Book Medical Publishers Inc, 1979.

The text has been prepared from papers presented at the Fourth Annual Burn Symposium conducted by the Burn Team of the Children's Hospital, Denver. It consists of 11 chapters prepared by 15 authors, and deals with special problems encountered in the care of children with burns. The text emphasizes that children are not miniature adults and have special physiological and psychological needs. Each chapter begins with a statement of objectives and concludes with a self-evaluation quiz. Answers to the quiz are provided at the end of the book. The book is approved as a home study textbook meeting the criteria for 12 credit hours in category 1 for the Physician's Recognition Award of the American Medical Association.

Chapter 1 considers metabolic problems of burned children. In discussing fluid resuscitation, the author agrees with Baxter that the use of colloid is not necessary in the first 36 to 48 hours. He also considers different formulae for fluid resuscitation and concludes that the Parkland formula using 4 mL/kg per percent of body surface burned is appropriate. My own experience has been that use of the Parkland formula in both children and adults produces significant edema and fluid overload. A more appropriate level has been 3 mL/kg per percent of body surface burned. Metabolic effects of the burn that are accentuated in children are increase in evaporative water loss, elevated core temperature, increased metabolic rate and oxygen consumption, and increased catecholamine output. A discussion of the role of prostaglandins is presented and emphasis is placed on the increased nutritional needs of the burned child.

Chapter 2 is on pulmonary injury. The author describes the types of burns sustained by children and their effect on the respiratory system. Priorities for the evaluation and maintenance of the airway are reviewed. Factors that govern the cause and treatment of direct and indirect pulmonary injuries are outlined, as well as the symptoms, treatment, and mechanism of injury due to carbon monoxide poisoning. The author emphasizes that there is no evidence that corticosteroids reduce edema secondary to thermal injury and, indeed, they are contraindicated in burns that result from combustion of hydrocarbons. Causes of pulmonary infection are discussed and emphasis is placed on the maintenance of aseptic technique. Continued observation for respiratory failure is essential because treatment modalities may have significant respiratory consequences.

Chapter 3 deals with the diagnosis and control of sepsis. The cause and management of major sources of sepsis (ie, pulmonary, wound, and intravenous catheters) is discussed. Emphasis is placed on early debridement and the use of topical antimicrobial agents to control sepsis. Areas of controversy discussed are prophylactic systemic antibiotics, subeschar injection of antibiotics, excisional therapy at the time of sepsis, tangential excision, and the use of isolation techniques and laminar flow. With regard to prophylactic antibiotics, I agree that penicillin should not be used in the early phases of resuscitation, but that it should be used in the phase of grafting.

Chapter 4 is on the use of topical agents. The advantages and disadvantages of the various topical antimicrobials are outlined. Guidelines for selection of the topical agent and the treatment of various types of burns are given. The excellent eschar penetration of mafenide acetate is emphasized.

Chapters 5 and 6 deal with the problems of flammable fabrics. Factors that must be present for material to burn are outlined. The role of flame-retardant garments is discussed and emphasis is placed on the need for close supervision of activities of young children. The role of federal laws and regulations by the Consumer Protection Agency governing flame-retardant fabrics is outlined and, also, control of chemical toxicity of substances used to treat flame-retardant fabrics. Characteristics of the two types of flame-resistant fabrics are presented.

Chapter 7 is devoted to nursing care of the burned child. It is a detailed chapter designed to provide the nurse with specific guidelines and information for the administration of care to any burned person. Specific sections are devoted to those special considerations necessary for the care of a burned child. The chapter is the longest of the symposium, is very well organized, and presents the nursing care of the burned child within the framework of basic physiologic principles. It outlines in detail the anatomy and physiology of the skin, guidelines for estimation of the depth of burn and relationship of depth of burn, extent of burn, and medical history to burn survival. A careful outline of wound care is included.

Chapters 8 and 9 discuss the role of the child psychiatrist and social worker in the care of the burned child. The stages of hospitalization are outlined and the effects on the family in each of the stages are discussed. The stages presented are (1) impact, (2) recoil, and (3) restitution. The second stage of recoil is the most difficult. This is the stage when fear, guilt, and anger surface. Depression may also occur during this stage. It is emphasized that children who sustain burns tend to have had more problems prior to burn than are normally found in children. Also stressed is the fact that interaction between patients is helpful. It seems that children do better in their own environment rather than in an adult burn environment. I have not found this to be of particular importance in my own experience.

The social worker is primarily involved with the dynamics of the family crisis when the burn occurs and planning the long-term follow-up when the patient returns to the community. The crisis period is discussed in some detail.

Chapter 10 deals with the nurse-family relationship. The role of the nurse is defined, the concept of a support system in the nurse-family interaction is outlined, and the mechanisms to relate the support system or network to the role of the nurse in the nurse-family relationship is stressed. As a coordinator of care, the nurse

deals not only with the family, but with all members of the burn team.

The final chapter discusses the reconstructive problems of the burn patient. The indications for reconstruction are (1) contracture, (2) ulceration, and (3) appearance. Improvement of function assumes top priority. However, a most difficult problem is to maintain realistic expectations on the part of the patient and doctor about the final appearance of the patient. Techniques of skin grafting are discussed and problems related to reconstruction of specific anatomic areas are outlined. Special sections deal with electrical burns of the mouth and full thickness burns. Emphasis is placed on the fact that surgery of burn patients is not only technical, but also psychotherapeutic.

This book on pediatric burns is a useful addition to the library of any member of the pediatric burn team. It should be emphasized that it is not a textbook of burn therapy, but rather explores issues peculiar to the care of burned children.

ELETHEA H. CALDWELL, MD

Histology of the Fetus and Newborn, by Marie Valdes-Dapena, 654 pp, with illus, Philadelphia, WB Saunders Co, 1979.

For the pathologist, it is often difficult to interpret pathologic findings from infants because of the difference in the histologic structures that these immature organisms display. More difficult still is the assessment of the degree of maturity in premature infants or in stillborns. Such differential diagnosis may be critical for the correct interpretation of growth retardation and certain congenital anomalies. Although sporadic papers on certain aspects of the histologic development exist and the topic finds superficial treatment in some pathology texts, no comprehensive work exists to aid the pathologist in his task.

This, then, is a welcome addition to our libraries. From her vast experience with perinatal pathology, Dr Valdes-Dapena has carefully selected a plethora of relevant pictures to document the structure of all organs in the human infant. The book is divided into 14 organ systems and 34 chapters. Each chapter is introduced by a succinct embryologic history of the organ, which is followed by a brief anatomical consideration. This is followed by a description of the salient histologic features. The photographs are carefully chosen and documented, with such data as fetal weight, race, sex, gestational age, and length of survival. The excellence of the more than 500 histologic preparations must be admired. There is not a wrinkle in the sections, they are uniformly stained, well photographed, and show no postmortem autolytic changes. The black-and-white photographs are crisp and readily allow recognition of the features that are critical to the understanding of the organ's principal features. Of particular value to pathologists will be the finer details of the developmental changes that take place in the lung, kidney, and CNS. Similarly, such features as extramedullary hematopoiesis in various organs, the sequential changes that occur in endocrine organs, the ciliation of esophageal epithelium, and many other special structures of the developing fetus are well depicted. Although only few references are appended to each chapter, they are carefully chosen and suffice to gain access to the relevant literature. But such should rarely be necessary, as this is an all-encompassing treatise.

Dr Valdes-Dapena has rendered a great service to the training programs of pathologists by documenting the perinatal histology of the developing human organism most comprehensively. Pathologists should find the book very helpful in the interpretation of difficult material. The book will find a welcome home in all pathology departments and is strongly recommended to all who have an interest in the interpretation of perinatal pathologic material.

KURT BENIRSCHKE, MD
San Diego Zoo
PO Box 551
San Diego, CA 92112

The Parents' Medical Manual, by Glenn Austin, Julia Stone Oliver, and John C. Richards, 426 pp, $8.95 (paperback), $15.95 (hardcover), Englewood Cliffs, NJ, Prentice-Hall Inc, 1978.

Of modest size and pleasing format, this book is an excellent guide and reference for educated parents concerning medical problems of children. The authors state in the preface that more than 400 physicians were consulted in deciding what to include in the book, and they have succeeded in including an explanation for, and the home treatment of, most common illnesses of childhood. It is hoped that sales will not be curtailed by a most unfortunate dust jacket. Prevention is stressed, not only in the first chapter entitled "Preventing Accidents and Poisonings," but throughout the book.

On seeing a listing of 70 contributing authors for a book of about 400 pages, one fears finding a hodgepodge of writing styles and a variability in quality of chapters. Such is not the case here as the contributions are distributed fleetingly in the text, sometimes in a few sentences and at other times in several pages. These contributions have been edited for smoothness. An example of how this works is seen at the outset of the chapter entitled, "The Mouth and Its Contents: Teeth and Braces, Thumb or Pacifier!" The author writes, "I asked my dentist, Dr. Frank McDaniel, DDS, 'How can you prevent dental bills?' He responded with the following advice." What follows is two clearly written pages on dental care of children. This unusual method of using edited contributions is skillfully done.

A contributing author is credited with the writing of only one chapter of the 22 in the book. Claude Frazier, MD, the pediatric allergist, has a chapter entitled "Stinging, Biting and Pesky Insects." There are some interesting photographs here as well as in some other chapters, and line drawings are used effectively throughout the book.

Organization of the material in this work deserves praise. Part I, entitled "Basic Home Health Responsibilities," is followed by "Illness: The Location," consisting of 11 chapters. This in turn is followed by six chapters on "Illness: The Cause." Part 4 is a group of "Medical Lists," including such things as information on poisonous plants; minerals and vitamins; food, drug, and cosmetic additives; a gluten diet.

The senior author, Glen Austin, a practicing pediatrician in Los Altos, Calif, worked on this book for five years. He deserves thanks from colleagues who may find their daily tasks a little easier if parents use it.

PAIN GONE

while the antibiotic gets going

An effective adjuvant to systemic antibiotic treatment, AURALGAN promptly relieves the pain and reduces the inflammation of acute otitis media, while the antibiotic of choice fights the infection.

AURALGAN contains the topical analgesic action of benzocaine and antipyrine plus glycerin dehydrated...a decongestant so hygroscopic that it "blots up" excess moisture through the tympanic membrane, for relief of pressure and pain in the middle ear.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
AURALGAN® Otic Solution
Each ml contains:

Antipyrine	54.0 mg
Benzocaine	14.0 mg
Glycerin dehydrated q.s. to	1.0 ml

(contains not more than 1.0% moisture) (also contains oxyquinoline sulfate)

INDICATIONS: *Acute otitis media of various etiologies*
—prompt relief of pain and reduction of inflammation in the congestive and serous stages
—adjuvant therapy during systemic antibiotic administration for resolution of the infection

CONTRAINDICATIONS: Hypersensitivity to any of the components or substances related to them./In the presence of spontaneous perforation or discharge.

DOSAGE AND ADMINISTRATION: *Acute otitis media:* Instill AURALGAN, permitting the solution to run along the wall of the canal until it is filled. Avoid touching the ear with dropper. Then moisten a cotton pledget with AURALGAN and insert into meatus. Repeat every one to two hours until pain and congestion are relieved.

HOW SUPPLIED: No.1000—AURALGAN® Otic Solution, in package containing 15 ml (½ fl oz) bottle with separate dropper-screw cap attachment.

...in acute otitis media

Auralgan®

OTIC SOLUTION

FULLY COMPATIBLE WITH SYSTEMIC ANTIBACTERIAL THERAPY. ON PRESCRIPTION ONLY.

Advertising and Subscription Information

Advertising Offices: 535 N Dearborn St, Chicago, IL 60610, Area Code 312, 751-6675; and 600 Third Ave, New York, NY 10016, Area Code 212, 867-6640.

Advertising Principles: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request.

Subscription Rates: The yearly rates for the AMERICAN JOURNAL OF DISEASES OF CHILDREN is as follows: for members of the AMA, $1.50, included in the annual membership dues; for non-members, $24 for one year, $40 for two years in the United States and US possessions; all other countries, $34 for one year, $60 for two years. Special yearly price to residents, interns, and medical students in the United States and US possessions, one year, $12; two years, $20. Address all subscription communications to Circulation-Fulfillment Department. Phone: 312, 751-6079.

Change of Address: POSTMASTER, send address changes to Helen R. Mazur, Director, Circulation-Fulfillment. Notification of address changes should be sent at least six weeks in advance, including both old and new address, and a mailing label taken from the most recent copy. Include your new zip code number.

AMERICAN JOURNAL OF DISEASES OF CHILDREN (ISSN 0002-922X) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

a better life with Depakene®
Valproic Acid

For your patients with mixed seizures including absence, or pure absence

More than just effective seizure control[1]

In 28 studies of patients with mixed grand mal and absence, 76% of all patients gained significant improvement; over one-third became seizure-free. In 60 studies involving pure absence, 86% of patients were improved; half became seizure-free.

Freedom from social stigmata is important too

With Depakene, social function is unimpeded by drug-induced hirsutism or gingival hyperplasia. Intellectual function may improve as more sedative drugs are reduced in dosage or withdrawn. Patients may be able to lead a more normal life with Depakene than was possible with their previous drug regimen.

A widely useful anticonvulsant

Depakene is indicated as sole or adjunctive therapy in both simple and complex absence seizures. It is also indicated for adjunctive treatment of patients with multiple seizure types which include absence. Clinical response has been especially noteworthy among patients with generalized tonic-clonic attacks, or with minor motor seizures (e.g., myoclonic movements, akinetic seizures), where combined with absence.

Offering your patients a chance for a better life

Sustained freedom from seizures can mean a drivers license, an active social schedule, involvement in athletic competition—a better life for your patient. Depakene has not been associated with hirsutism or gingival hyperplasia. Sedation has not been a frequent problem. The most common side effect with Depakene is G.I. upset, which usually responds to temporary dosage reduction. Serious side effects, including fatal hepatitis, have occurred.

1. Worldwide studies of Depakene experience (Data refer only to grand mal and/or absence seizures. Since each type was evaluated separately, some patients appear in both groups. Though most of these studies were uncontrolled and had widely differing protocols, their collective data clearly support efficacy of the drug).

See overleaf for brief summary of prescribing information

Abbott Laboratories,
North Chicago, Illinois 60064

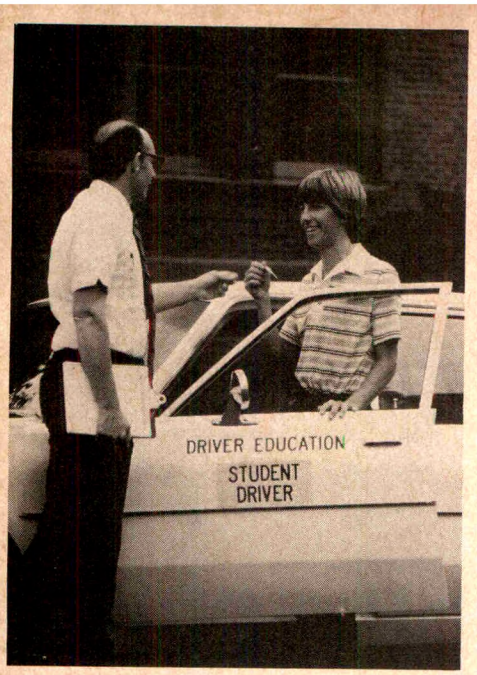
Depakene®
Valproic Acid

Capsules 250 mg;
Syrup 250 mg/5 ml

Depakene®
Valproic Acid



Offering a chance for a better life for your patients with mixed seizures including absence, or pure absence

A BRIEF SUMMARY OF PRESCRIBING INFORMATION

INDICATIONS: DEPAKENE (valproic acid) is indicated for use as sole and adjunctive therapy in the treatment of simple and complex absence seizures, including petit mal. DEPAKENE may also be used adjunctively in patients with multiple seizure types which include absence seizures.

In accordance with the International Classification of Seizures, simple absence is defined as very brief clouding of the sensorium or loss of consciousness (lasting usually 2-15 seconds), accompanied by certain generalized epileptic discharges without other detectable clinical signs. Complex absence is the term used when other signs are also present.

CONTRAINDICATIONS: DEPAKENE (valproic acid) is contraindicated in patients with known hypersensitivity to the drug.

WARNINGS: Hepatic failure resulting in fatalities has occurred in patients receiving DEPAKENE. These incidences usually have occurred during the first six months of treatment with DEPAKENE. Liver function tests should be performed prior to therapy and at frequent intervals thereafter. Caution should be observed when administering DEPAKENE to patients with pre-existing hepatic disease.

The drug should be discontinued immediately in the presence of significant hepatic dysfunction, suspected or apparent. The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increasing the dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher dosages.

Usage in Pregnancy: THE EFFECTS OF DEPAKENE IN HUMAN PREGNANCY ARE UNKNOWN. ANIMAL STUDIES HAVE DEMONSTRATED TERATOGENICITY.

Studies in rats demonstrated placental transfer of the drug. Doses greater than 65 mg/kg/day given to pregnant rats and mice produced skeletal abnormalities in the offspring, primarily involving ribs and vertebrae; doses greater than 150 mg/kg/day given to pregnant rabbits produced fetal resorptions and (primarily) soft-tissue abnormalities in the offspring. In rats a dose-related delay in the onset of parturition was noted. Postnatal growth and survival of the progeny were adversely affected, particularly when drug administration spanned the entire gestation and early lactation period.

THERE ARE MULTIPLE REPORTS IN THE CLINICAL LITERATURE WHICH INDICATE THAT THE USE OF ANTICONVULSANT DRUGS DURING PREGNANCY RESULTS IN AN INCREASED INCIDENCE OF BIRTH DEFECTS IN THE OFFSPRING. ALTHOUGH DATA ARE MORE EXTENSIVE WITH RESPECT TO TRIMETHADIONE, PARAMETHADIONE, PHENYTOIN, AND PHENOBARBITAL, REPORTS INDICATE A POSSIBLE SIMILAR ASSOCIATION WITH THE USE OF OTHER ANTICONVULSANT DRUGS. THEREFORE, ANTICONVULSANT DRUGS SHOULD BE ADMINISTERED TO WOMEN OF CHILDBEARING POTENTIAL ONLY IF THEY ARE CLEARLY SHOWN TO BE ESSENTIAL IN THE MANAGEMENT OF THEIR SEIZURES.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

PRECAUTIONS: *Hepatic dysfunction:* See WARNINGS.

General: Because of reports of thrombocytopenia and platelet aggregation dysfunction, platelet counts and bleeding time determination are recommended before initiating therapy and at periodic intervals. It is recommended that patients receiving DEPAKENE be monitored for platelet count prior to planned surgery. Clinical evidence of hemorrhage, bruising or a disorder of hemostasis/coagulation is an indication for reduction of DEPAKENE dosage or withdrawal of therapy pending investigation.

Since DEPAKENE (valproic acid) may interact with concurrently administered anticonvulsant drugs, periodic serum level determinations of concomitant anticonvulsant drugs are recommended during the early course of therapy. (See Drug Interactions).

DEPAKENE is partially eliminated in the urine as a keto-metabolite which may lead to a false interpretation of the urine ketone test.

Information For Patients: Since DEPAKENE may produce CNS depression, especially when combined with another CNS depressant (e.g., alcohol), patients should be advised not to engage in hazardous occupations, such as driving an automobile or operating dangerous machinery, until it is known that they do not become drowsy from the drug.

Drug Interactions: DEPAKENE may potentiate the CNS depressant activity of alcohol.

THERE IS EVIDENCE THAT DEPAKENE MAY CAUSE AN INCREASE IN SERUM PHENOBARBITAL LEVELS, ALTHOUGH THE MECHANISM OF THE INTERACTION IS UNKNOWN. ALL PATIENTS RECEIVING CONCOMITANT BARBITURATE THERAPY SHOULD BE CLOSELY MONITORED FOR NEUROLOGICAL TOXICITY, SERUM BARBITURATE DRUG LEVELS OBTAINED, IF POSSIBLE, AND THE BARBITURATE DOSAGE DECREASED, IF APPROPRIATE.

Primidone is metabolized into a barbiturate and, therefore, may also be involved in a similar or identical interaction.

THERE IS CONFLICTING EVIDENCE REGARDING THE INTERACTION OF DEPAKENE WITH PHENYTOIN. IT IS NOT KNOWN IF THERE IS A CHANGE IN UNBOUND (FREE) PHENYTOIN SERUM CONCENTRATIONS. THE DOSAGE OF PHENYTOIN SHOULD BE ADJUSTED AS REQUIRED BY THE CLINICAL SITUATION.

THE CONCOMITANT USE OF VALPROIC ACID AND CLONAZEPAM MAY PRODUCE ABSENCE STATUS.

Caution is recommended when DEPAKENE (valproic acid) is administered with drugs affecting coagulation, e.g., aspirin and warfarin. (See ADVERSE REACTIONS).

Carcinogenesis, Mutagenesis: There has been insufficient study of the drug in animals to determine whether it has carcinogenic potential. Carcinogenicity studies in rats and mice are currently in progress.

Mutagenesis studies on DEPAKENE have been performed using bacterial and mammalian systems. These studies have provided no evidence of a mutagenic potential for DEPAKENE.

Pregnancy: See WARNINGS.

Nursing Mothers: DEPAKENE is excreted in breast milk. It is not known what effect this would have on a nursing infant. As a general rule, nursing should not be undertaken while a patient is receiving DEPAKENE.

Fertility: Chronic toxicity studies in juvenile and adult rats and dogs demonstrated reduced spermatogenesis and testicular atrophy at doses greater than 200 mg/kg/day in rats and greater than 90 mg/kg/day in dogs. Segment I fertility studies in rats have shown doses up to 350 mg/kg/day for 60 days to have no effect on fertility. THE EFFECT OF DEPAKENE (VALPROIC ACID) ON THE DEVELOPMENT OF THE TESTES AND ON SPERM PRODUCTION AND FERTILITY IN HUMANS IS UNKNOWN.

ADVERSE REACTIONS: Since DEPAKENE (valproic acid) has usually been used with other anticonvulsant drugs, it is not possible, in most cases, to determine whether the following adverse reactions can be ascribed to DEPAKENE alone, or the combination of drugs.

Gastrointestinal: The most commonly reported side effects at the initiation of therapy are nausea, vomiting and indigestion. These effects are usually transient and rarely require discontinuation of therapy. Diarrhea, abdominal cramps and constipation have been reported. Both anorexia with some weight loss and increased appetite with weight gain have also been reported.

CNS Effects: Sedative effects have been noted in patients receiving valproic acid alone but are found most often in patients receiving combination therapy. Sedation usually disappears upon reduction of other anticonvulsant medication. Ataxia, headache, nystagmus, diplopia, asterixis, "spots before eyes", tremor, dysarthria, dizziness, and incoordination have rarely been noted. Rare cases of coma have been noted in patients also on phenobarbital.

Dermatologic: Transient increases in hair loss have been observed. Skin rash and petechiae have rarely been noted.

Psychiatric: Emotional upset, depression, psychosis, aggression, hyperactivity and behavioral deterioration have been reported.

Musculoskeletal: Weakness has been reported.

Hematopoietic: Thrombocytopenia has been reported. Valproic acid inhibits the secondary phase of platelet aggregation. (See DRUG INTERACTIONS). This may be reflected in altered bleeding time. Bruising, hematoma formation and frank hemorrhage have been reported. Relative lymphocytosis and hypofibrinogenemia have been noted. Leukopenia and eosinophilia have also been reported.

Hepatic: Increases in serum alkaline phosphatase and elevations of serum glutamic oxaloacetic transaminase (SGOT) have been noted. Elevation of SGOT may be dose related. Elevations of SGPT and LDH have been noted less frequently. Isolated cases of severe hepatotoxicity have been reported but do not appear dose related. (See WARNINGS).

OVERDOSAGE: A single case of overdosage with valproic acid has been reported. After ingesting 36 grams in combination with phenobarbital and phenytoin, the patient presented in deep coma. An electroencephalogram recorded diffuse slowing, compatible with the state of consciousness. The patient made an uneventful recovery.

Since DEPAKENE is absorbed very rapidly, gastric lavage may be of limited value. General supportive measures should be applied with particular attention being given to the maintenance of adequate urinary output.

DOSAGE AND ADMINISTRATION: DEPAKENE (valproic acid) is administered orally. The recommended initial dose is 15 mg/kg/day, increasing at one week intervals by 5 to 10 mg/kg/day, until seizures are controlled or side effects preclude further increases. The maximum recommended dosage is 60 mg/kg/day. If the total daily dose exceeds 250 mg, it should be given in a divided regimen.

The frequency of adverse effects (particularly elevated liver enzymes) may increase with increasing dose. Therefore, the benefit gained by increased seizure control by increased dosage must be weighed against the increased incidence of adverse effects sometimes seen at higher doses.

The following table is a guide for the initial daily dose of DEPAKENE (valproic acid) (15 mg/kg/day):

Weight (kg)	Weight (lb)	Total Daily Dose (mg)	Number of Capsules or Teaspoonfuls of Syrup Dose 1	Dose 2	Dose 3
10 - 24.9	22 - 54.9	250	0	0	1
25 - 39.9	55 - 87.9	500	1	0	1
40 - 59.9	88 - 131.9	750	1	1	1
60 - 74.9	132 - 164.9	1,000	1	1	2
75 - 89.9	165 - 197.9	1,250	2	1	2

A good correlation has not been established between daily dose, serum level and therapeutic effect, however, therapeutic serum levels for most patients will range from 50 to 100 mcg/ml. Occasional patients may be controlled with serum levels lower or higher than this range.

As the DEPAKENE dosage is titrated upward, blood levels of phenobarbital and/or phenytoin may be affected. (See PRECAUTIONS).

Patients who experience G.I. irritation may benefit from administration of the drug with food or by slowly building up the dose from an initial low level.

THE CAPSULES SHOULD BE SWALLOWED WITHOUT CHEWING TO AVOID LOCAL IRRITATION OF THE MOUTH AND THROAT.

HOW SUPPLIED: DEPAKENE (valproic acid) is available as orange-colored soft gelatin capsules of 250 mg valproic acid in bottles of 100 capsules (**NDC** 0074-5681-13), and as a red syrup containing the equivalent of 250 mg valproic acid per 5 ml as the sodium salt in bottles of 16 ounces (**NDC** 0074-5682-16).

How Supplied

CYCLAPEN® (cyclacillin) tablets:
250 mg scored tablets
500 mg scored tablets

CYCLAPEN® (cyclacillin) for oral suspension
125 mg per 5 ml:
100 ml and 200 ml bottles
250 mg per 5 ml:
100 ml and 200 ml bottles

Indications

Cyclapen® (cyclacillin) has less in vitro activity than other drugs in the ampicillin class of antibiotics and its use should be confined to the indications listed below.

Cyclapen® is indicated for the treatment of the following infections:

RESPIRATORY TRACT
Tonsillitis and pharyngitis caused by Group A beta-hemolytic streptococci
Bronchitis and pneumonia caused by *S. pneumoniae* (formerly *D. pneumoniae*)
Otitis Media caused by *S. pneumoniae* (formerly *D. pneumoniae*) and *H. influenzae*
Acute exacerbation of chronic bronchitis caused by *H. influenzae**

*Though clinical improvement has been shown, bacteriologic cures cannot be expected in all patients with chronic respiratory disease due to *H. influenzae*.

SKIN AND SKIN STRUCTURES (integumentary) infections caused by Group A beta-hemolytic streptococci and staphylococci, non-penicillinase producers.

URINARY TRACT INFECTIONS caused by *E. coli* and *P. mirabilis*. (This drug should not be used in any infections caused by *E. coli* and *P. mirabilis* other than urinary tract infections.)

NOTE: Cultures and susceptibility tests should be performed initially and during treatment to monitor the effectiveness of therapy and the susceptibility of bacteria. Therapy may be instituted prior to the results of sensitivity testing.

Contraindications

The use of this drug is contraindicated in individuals with a history of an allergic reaction to penicillins.

Warnings

CYCLACILLIN SHOULD ONLY BE PRESCRIBED FOR THE INDICATIONS LISTED IN THIS INSERT.

CYCLACILLIN HAS LESS *IN VITRO* ACTIVITY THAN OTHER DRUGS OF THE AMPICILLIN CLASS ANTIBIOTICS. HOWEVER, CLINICAL TRIALS HAVE DEMONSTRATED THAT IT IS EFFICACIOUS FOR THE RECOMMENDED INDICATIONS.

SERIOUS AND OCCASIONAL FATAL HYPERSENSITIVITY (ANAPHYLACTOID) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING PENICILLIN.

ALTHOUGH ANAPHYLAXIS IS MORE FREQUENT FOLLOWING PARENTERAL ADMINISTRATION, IT HAS OCCURRED IN PATIENTS ON ORAL PENICILLINS. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS. THERE ARE REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY REACTIONS WHO EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH A CEPHALOSPORIN. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE ABOUT PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, THE DRUG SHOULD BE DISCONTINUED AND APPROPRIATE THERAPY SHOULD BE INITIATED. SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN, INTRAVENOUS STEROIDS, AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

Precautions

Prolonged use of antibiotics may promote the overgrowth of nonsusceptible organisms. If superinfection occurs during therapy, appropriate measures should be taken.

PREGNANCY: Pregnancy Category B. Reproduction studies have been performed in mice and rats at doses up to ten times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cyclacillin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

NURSING MOTHERS: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when cyclacillin is administered to a nursing woman.

Adverse Reactions

The oral administration of cyclacillin is generally well tolerated.

As with other penicillins, untoward reactions of the sensitivity phenomena are likely to occur, particularly in individuals who have previously demonstrated hypersensitivity to **penicillins** or in those with a history of allergy, asthm fever, or urticaria.

The following adverse reactions have been reported with the use of cycla diarrhea (in approximately 1 out of 20 patients treated), nausea and vo (in approximately 1 in 50), and skin rash (in approximately 1 in 60). Is instances of headache, dizziness, abdominal pain, vaginitis, and urticari been reported. (See WARNINGS)

Other less frequent adverse reactions which may occur and that have reported during therapy with other penicillins are: anemia, thrombocyto thrombocytopenic purpura, leukopenia, neutropenia and eosinophilia. reactions are usually reversible on discontinuation of therapy.

As with other semisynthetic penicillins, SGOT elevations have been repo

Dosage and Administration

INFECTION*	ADULTS	CHILDREN
		Dosage should not in a dose higher thar for adults.
Respiratory Tract		
Tonsillitis & Pharyngitis**	250 mg q.i.d. in equally spaced doses	body weight <20 k lbs) 125 mg q.i. equally spaced dose body weight >20 k lbs) 250 mg q.i. equally spaced dose
Bronchitis and Pneumonia		
Mild or Moderate Infections	250 mg q.i.d. in equally spaced doses	50 mg/kg/day q.i. equally spaced dose
Chronic Infections	500 mg q.i.d. in equally spaced doses	100 mg/kg/day q.i. equally spaced dose
Otitis Media	250 mg to 500 mg q.i.d. in equally spaced doses depending on severity	50 to 100 mg/kg/d equally spaced dose pending on severity
Skin & Skin Structures	250 mg to 500 mg q.i.d. in equally spaced doses depending on severity	50 to 100 mg/kg/d equally spaced dose pending on severity
Urinary Tract	500 mg q.i.d. in equally spaced doses	100 mg/kg/day in eq spaced doses.

*As with antibiotic therapy generally, treatment should be continued minimum of 48 to 72 hours after the patient becomes asymptomatic or evidence of bacterial eradication has been obtained.

**In infections caused by Group A beta-hemolytic streptococci, a minimu 10 days of treatment is recommended to guard against the risk of rheur fever or glomerulonephritis.

In the treatment of chronic urinary tract infection, frequent bacteriologic clinical appraisal is necessary during therapy and may be required for se months afterwards.

Persistent infection may require treatment for several weeks.

Cyclacillin is not indicated in children under 2 months of age.

Patients with Renal Failure

Based on a dosage of 500 mg q.i.d., the following adjustment in do interval is recommended:

Patients with a creatinine clearance of >50 ml/min need no age interval adjustment.

Patients with a creatinine clearance of 30-50 ml/min should receiv doses every 12 hours.

Patients with a creatinine clearance of between 15-30 ml/min s receive full doses every 18 hours.

Patients with a creatinine clearance of between 10-15 ml/min s receive full doses every 24 hours.

In patients with a creatinine clearance of ≤10 ml/mi serum creatinine values of ≥ 10 mg %, serum cyclacillin levels are re mended to determine both subsequent dosage and frequency.

Wyeth Laboratories
Philadelphia, Pa. 19101

"He was allergic to cow's milk. And soy milk. So our doctor prescribes Meyenberg Goat Milk."

Because there is no substitute for real milk.

Since the offending antigen in cow's milk is usually lactalbumin, a specific protein, Meyenberg Goat Milk has frequently proven a practical and successful substitute for cow's milk. Goat milk does not deprive the infant of the important and irreplaceable values of milk, such as occurs when synthetic milk formulas are used.

Meyenberg Goat Milk is nutritionally equal to cow's milk in protein, carbohydrate, and fat. It contains no crude fibers or other extraneous materials which cause digestive upset.

Available in Evaporated and Powdered form. Send the enclosed coupon for further information and a full-size can. Meyenberg™ BRAND

Yes, please ☐ send a free sample.

Return this coupon and we'll send you a full-size can of evaporated goat milk by return mail.

Instructions for Authors

General Information.—Send manuscripts by first-class (**not** registered) mail to the Chief Editor, Gilbert B. Forbes, MD, Box 777, 601 Elmwood Ave, Rochester, NY 14642. Designate one author as correspondent and provide his/her address and telephone number. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the *American Journal of Diseases of Children* and may not be published elsewhere without permission from the publisher (AMA).

In view of the provisions of *The Copyright Revision Act of 1976*, effective Jan 1, 1978, the author(s) of manuscripts, letters to the editor, and book reviews accepted for publication in the JOURNAL will be required to sign and date the following statement: "In consideration of the AMA taking action in reviewing and editing my/our submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."

Manuscript Preparation

All the elements of a manuscript should be submitted in **triplicate, double-spaced throughout.** Use heavy-duty white bond paper, 22 × 28-cm, and 4-cm margins. The style of writing should conform to proper English usage and syntax. All measurements are to be in metric units, temperatures in Centigrade.

All accepted manuscripts are subject to copy editing. The corresponding author will receive an edited typescript and layout for approval. Forms for ordering reprints are included with the edited typescript. Proofs will be sent for approval if requested by the author and if printing deadlines permit. The author is responsible for all statements in his/her work, including changes made by the copy editor.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines. The title page should include the full names and academic affiliations of all authors, the address to which requests for reprints should be sent, and, if the manuscript was presented at a meeting, the name of the organization, place, and date on which it was read.

Abstract.—Provide an abstract (135-word maximum) of the article, including statement of the problem, method of study, results, and conclusions. The abstract replaces the summary.

Informed Consent.—Manuscripts reporting the results of experimental investigations on humans must include a statement to the effect that informed consent was obtained from the parents or guardians after the nature of the procedure(s) had been fully explained.

Clinical Memoranda

Brief accounts of interesting observations and clinical situations. Limited to 800 words plus one table or illustration; abstract unnecessary. Submit in triplicate, double-spaced. Copyright assignment required.

Letters to the Editor

Correspondence pertaining to material published in the JOURNAL. Limit 500 words. Submit in triplicate, double-spaced, and clearly marked "For publication." Copyright assignment required.

References

These must be listed in order of their appearance in the text, and typed double-spaced, in the following manner:

1. Applebaum MM, Thaler MM: Reye syndrome without initial hepatic involvement. *Am J Dis Child* 131:295-296, 1977.
2. Koller LR: *Ultraviolet Radiation*, ed 2. New York, John Wiley & Sons Inc, 1965, pp 141-160.
3. Daughaday WH: The adenohypophysis, in Williams RH (ed): *Textbook of Endocrinology*, ed 5. Philadelphia, WB Saunders Co, 1974, pp 31-79.

Do not include unpublished data, personal communications, or manuscripts "in preparation" or "submitted" in the list of references. Such material, if essential, may be incorporated in the body of the article.

Illustrations

Submit in triplicate, unmounted, and untrimmed. Send only high contrast glossy prints (not photocopies or original artwork); preferred size 12.5 × 18-cm. Figure number, name of first author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. Lettering must be legible after reduction to column size. Magnification and stain should be provided for histologic sections.

For illustrations in full color submit 35-mm, positive color transparencies, mounted in cardboard and carefully packaged. Do not submit glass-mounted transparencies; do not submit color prints. The fee is $275 for up to six square-finished color illustrations that can be arranged on one page.

Legends.—Legends for illustrations should be typed double-spaced, beginning on a separate sheet of paper (40-word maximum for each).

Acknowledgments.—Illustrations and tables from other publications must be suitably acknowledged, and accompanied by written permission from publisher and author.

Photographic Consents.—A signed statement of consent from **both** parents (or guardian) or the persons involved must accompany all photographs of patients in which a possibility of identification exists. It is not sufficient to cover the eyes to mask identity.

Tables.—Each table should be typed double-spaced, including all headings, on a separate sheet of 22 × 28-cm paper. If a table must be continued, use a second sheet and repeat all heads. Each table must have a title.

Recurrent Abdominal Pain in Childhood

Recent studies report recurrent abdominal pain in childhood as an indication for upper endoscopy. The use of this procedure or exploratory laparotomy in children with recurrent abdominal pain[1,2] has prompted the following reappraisal.

There is a confusion in the diagnosis and management of recurrent abdominal pain. Specifically, there is no clear definition of recurrent abdominal pain and there is only vague knowledge of its etiology. No diagnostic markers have been elucidated, no proved effective treatment is available, and no prospective studies of outcome have been performed.

No one has clearly defined recurrent abdominal pain. Apley[3] emphasized the presence of three discrete episodes of abdominal pain occurring over a minimum of a three-month period and interfering with the regular activities and school attendance of the child. Not addressed were considerations of the quality of the pain, duration of each episode, alleviating factors, physical condition between episodes, and absence of certain specific symptoms and signs.

Other authors[4] have applied even less stringent diagnostic criteria and have applied different terms in an attempt to explain the cause or association of the abdominal pain. Irritable colon, psychogenic abdominal pain, and allergic fatigue syndrome are some of the synonyms.[5] On the whole, they stress the vagueness of the entity and the psychological components.

Children with recurrent abdominal pain have a high frequency of behavioral and personality disorders,[3] along with some evidence of maladjustment and anxiety reactions.[6] They tend to be high-strung perfectionists and have apprehensive personalities.[3,7] Many have past histories of colic and feeding problems in infancy, and there is frequently a family history of abdominal pain among parents and relatives.[3,7] In addition, a high incidence of stressful situations within the family and at school occurs in children with recurrent abdominal pain. Despite these clinical impressions, very few studies have been conducted to establish the extent of these problems in comparison with controls. Certainly children without recurrent abdominal pain are subjected to similar stresses, and one wonders what the ultimate determinants of pain in these children are.

Various theories have been proposed to explain the pathophysiology. Abnormal pupillary dilation to stress[8] and excessive rectosigmoid spasm to neostigmine bromide[9] were described to implicate autonomic dysfunction as a possible mechanism involved in recurrent abdominal pain. It was also stated[10] that lactose malabsorption may play a part and that elimination of milk and dairy products may help. At present further work is needed in this area.

The greatest dilemma is that recurrent abdominal pain can be a symptom of both psychosomatic and organic disease. However, in a follow-up study by Stickler and Maryly[1] overt organic disease had developed in only three of 161 patients (2%) over a six- to seven-year period. Weight loss or anemia were noted retrospectively in two of three children with suspected inflammatory bowel disease. Therefore, we suggest that those children with recurrent abdominal pains have a thorough history and physical examination. Those who have no additional symptoms to suggest organic disease, no tenderness, and no pain interfering with sleep or pleasurable activities should have a minimum of diagnostic tests. Loss of weight and anemia can be signs of organic disease.[1] Several follow-up visits are needed for the pediatrician to become familiar with the patient, parents, and the environmental situation of the child. Tests performed may include urinalysis, urine culture, hemoglobin count, WBC count, ESR, and stool examination for occult blood. However, at times the parents and consequently the physician may become enmeshed in a seemingly never-ending effort to find a physical cause for the symptoms.[11] The long list of diagnostic efforts include electroencephalography, gastrointestinal barium studies, intravenous pyelograms, computerized tomographic scans, echograms, cholecystography, endoscopy, and proctoscopy. Most disturbing are the instances of exploratory laparotomies performed to rule out a possible organic disease.[1,2]

Our experience suggests that attempts at treatment with placebos are not to be recommended. Antispasmotics and sedatives may contribute to the anxiety and confuse the picture. Reassurance of the patient and family that organic disease is not the cause of recurrent abdominal pain is most helpful and in certain instances, is all that need be done. Explanation that the pain is in fact real and not imagined and that it is a normal psychosomatic reaction to stress is usually accepted. It is most helpful to be positive, reassuring, and understanding. We persuade the parents that immediate return to school is mandatory.

In the more refractory and long-standing cases, parental acceptance of a nonorganic functional etiology will be difficult unless the child is hospitalized and many of the aforementioned tests are performed. When the family accepts the idea that this disorder has no organic cause, the physician may

attempt to find and alleviate the cause of the stress. This will take time, concerned interest, and emotional support. Elective referral to psychosocial professionals may be necessary. It is important to emphasize that if the situation is not properly handled, an endless number of diagnostic tests may be performed, or the phenomenon of "physician shopping" may needlessly occur. It is this phenomenon that many times leads to extensive, often unnecessary evaluations, and to exploratory laparotomy. The pediatrician has the main responsibility of assuring the family of the benign course of the entity and preventing deplorable practices, such as exploratory laparotomy.

In conclusion, there is a need for a clear definition of recurrent abdominal pain, indications for diagnostic evaluation, and instruction in approach and treatment. Long-term controlled studies regarding the outcome of the disease, with and without intervention, are necessary for better understanding and management.

The Alternative Birthing Center

One Family's Experience

I have been editing copy for the JOURNAL for more than a year. In that time, I've edited case reports, poems, letters, book reviews, and editorials, by dozens of authors, practically all of them with one theme: wonder before the human body and the countless ways that it can malfunction. This, of course, reflects medicine's preoccupation with sickness. However, a recent event reminded me that a physician can be concerned with the preservation of health as well as with curing sickness, to help the patient through a difficult period with grace. This event was the birth of my daughter last April in an "alternative birthing center" in Chicago.

When my wife, Anne Ryan, learned in September 1978 that she was pregnant, she had already investigated the subject of childbirth both as it takes place in the hospital and the alternatives to hospital birth. One of my nieces had been delivered at home by an obstetrician and, as we discovered, few of the popular books on the subject had anything good to say about a hospital delivery. The complaints against hospital delivery are well known, but for us they were new and frightening. Separation of husband from wife and parent from child, the liberal use of powerful drugs, routine cutting, the high incidence of cesarean sections, all seemed to us to indicate a lack of consideration toward parent and child.

On the other hand, a home delivery was not practical. Aside from the fact that getting medical assistance would be nearly impossible, having a first child at home seemed just too risky. Then we saw an article in a local newspaper about the Alternative Birthing Center (ABC) at Illinois Masonic Hospital, Chicago. The idea behind the ABC is to simulate the conditions of a home birth as much as possible, while having modern hospital equipment and trained personnel just steps away should anything go wrong. Each delivery takes place in a large "bedroom," with ordinary table, chairs, carpeting, record player, beanbag chair, bentwood rocker, and a king-sized bed. The father or a friend

of the mother assists at the birth, and other people can witness it. The baby is not taken away after birth, and, as much as possible, the wishes of the parents are respected with regard to the medical procedures performed.

Like most good things, however, the ABC has a catch: it only accepts mothers whose deliveries will be uncomplicated. That means no breech deliveries, no multiple births, no premature children, no children more than three weeks overdue, no prolonged labors, and no mothers who have already had a cesarean section. About one mother in four who begins labor in the ABC "washes out," and is transferred to the regular labor and delivery area. The thought that we might still wind up in a regular labor and delivery facility was disturbing, but we decided the reward was worth the risk, and so signed up and began our preparations.

First, we attended hospital prenatal classes, which taught about nutrition, exercise, labor, etc, and included a tour of the labor and delivery area. It was interesting to compare reactions to the cozy atmosphere of the ABC and the impersonal atmosphere of the regular labor and delivery area. The delivery room itself, with its cold tile walls and utilitarian delivery table, well-worn restraining straps hanging from its sides, was enough to convince several couples to inquire about the ABC.

Late in February we began Lamaze training with a group in the home of a registered nurse. The six weekly sessions covered standard Lamaze material: instruction in anatomy and recognition of the various stages of labor; breathing exercises with which to cope with labor; conversation with other young parents on what to expect; and practice in dealing with various aspects of labor. By the end of the six weeks, we felt we were ready.

Naturally, labor did not go according to the standard scenario. We were awakened by Anne's contractions at about 1 AM, strong contractions coming about every three minutes and lasting 90 to 110 s. After a few minutes of this, it was obvious that the labor had skipped the first stage and gone directly into transition-stage. While I made the phone calls, Anne was able to cope with the contractions with her breathing exercises; a friend then drove us to the hospital. To my mind, this is the most important lesson of our experience: if we had decided to have a traditional delivery, with everything left in the hands of the physician, we would not have been ready for a labor that came on that quickly and that hard. Without Lamaze training, we may well have panicked and turned a serious but manageable situation into a dangerous one.

By 2:30 AM we were at the hospital. Anne had already dilated to 9 cm and, naturally, was very irritable and in great discomfort. It is difficult to collect my thoughts about what happened during the next 2½ hours before the baby was born, mostly because I was very busy helping with the labor: helping Anne regulate her breathing, encouraging her ("verbal anesthesia," the Lamaze people call it), and helping her to a comfortable position. (Toward the end, she was most comfortable sitting on the bed with the beanbag chair supporting her back; she even delivered in that position.) My recollection is that time was somehow compressed, hours passing like minutes; also, I "remember" some things that could not possibly have happened; for example Anne wearing her street clothes during labor, when I know she must have been wearing a hospital gown.

The nurse-clinician helped us in many small ways. The obstetrician, Leticia Dacanay, MD, arrived around 3:00 AM, and after what seemed to be a short time Anne began to push. Spontaneously, we fell into a position in which she would hold my hands and pull while pushing; I would pull back and give her something to brace herself against. I could see a large lump descending, and finally a small tuft of hair appeared. Dr Dacanay laid out a pair of surgical gloves in case I wanted to catch the baby, but I was too busy helping Anne push to put them on.

A cut was needed. There was a great rush of fluid, then the baby's head appeared. I looked down at it, watched it slowly rotate; it seemed as if the infant was looking around at the world. Then one more push, and at 3:56 AM our daughter Marian skidded out onto the mattress. She was bluish at first, but pinked up nicely within a few minutes (Apgar scores of 6 and 9 at 1 and 5 minutes of life, if you're interested); quickly, Dr Dacanay and the nurse had her cord clamped and cut, her throat cleared, and the silver nitrate into her eyes.

And what seemed like a split second later (although it was at least ten minutes), I was picking her up. She seemed to be squinting, so I maneuvered her face into my shadow and her eyes jumped open. Then I gave her to Anne, who suckled her. Marian spent the day with us, and we took her home later that afternoon.

It is tempting to fashion a rule from all this; however, Marian's birth may not have been typical. The alternative birthing movement is a large one; it contains a few people who are irrationally hostile to physicians and modern medicine, and a few who insist on demonstrating once more that a little knowledge is a dangerous thing. However, some lessons can be learned from our experience, small points that, to a patient, seem to be forgotten in the daily hustle of medical care. First, an informed patient is better off than an ignorant one. Second, a patient who manages his own health as far as prudence allows will be better off than one whose health is managed for him. Third, a patient who is reasoned with will be more cooperative than one who is ordered around. Finally, patient involvement is economical: Illinois Masonic, for example, charges for the ABC about one third of what it charges for the regular labor and delivery area.

The birth of our daughter was one of the great experiences of our lives. It happened this way thanks largely to medical personnel who cared. I only hope that the alternative birthing movement's spirit of cooperation between patient and physician can be applied to every branch of American medicine.

RA27/3 Rubella Vaccine

A Four-Year Follow-up

Henry H. Balfour, Jr, MD; Karl E. Groth; Charlene K. Edelman

• **RA27/3 rubella vaccine was given to 418 subjects aged 1 to 17 years in 1974, 201 of whom participated in a four-year follow-up study. Two vaccine-associated complications were reported. A 5-year-old boy had transient arthritis of the hip, and a 1-year-old boy had a pigmented macule at the inoculation site. Rubella reinfection was uncommon, occurring at most in three of our subjects. All of the 186 susceptible children seroconverted, and 182 had hemagglutination-inhibiting (HI) titers of 8 or greater at four-year follow-up (geometric mean titer, 30.3). In the four children whose HI titers declined to undetectable levels, both HI and neutralizing (Nt) antibodies had developed immediately postimmunization, and two had Nt titers at follow-up despite loss of HI antibodies. RA27/3 vaccine boosted HI titers in 15 seropositive subjects, but titers returned to preimmunization levels four years later. We concluded that RA27/3 vaccine produced durable immunity with very low rates of rubella reinfection and secondary vaccine failure during the four years since immunization.**

(*Am J Dis Child* 134:350-353, 1980)

RA27/3 is the only rubella vaccine presently licensed and available in the United States. Since RA27/3 is now a part of routine pediatric immunizations in our country, it is important to document its long-term effectiveness in children. We immunized 418 children from Minnesota and Wisconsin with RA27/3 rubella vaccine in 1974.[1] A follow-up study was conducted in 1978, at which time we obtained histories of vaccine reactions and rubella-like illnesses and measured rubella serum antibody titers. We were especially interested in the percent of children with persistent rubella hemagglutination-inhibiting (HI) antibodies, because a 1977 investigation in suburban Minneapolis indicated that 58 (36%) of 159 children vaccinated with HPV77 DE5 strain rubella vaccine lacked HI titers when tested four years after immunization.[2]

From the Virology Section, Division of Clinical Microbiology, Department of Laboratory Medicine and Pathology (Dr Balfour, Mr Groth, Ms Edelman), and the Department of Pediatrics (Dr Balfour), University of Minnesota, Minneapolis.

Reprint requests to Box 437 Mayo, University of Minnesota Health Sciences Center, 420 Delaware St SE, Minneapolis, MN 55455 (Dr Balfour).

SUBJECTS AND METHODS

The subjects had been vaccinated subcutaneously during a field study of RA27/3 vaccine in 1974.[1] All who had been seronegative and some of those who had been seropositive prior to immunization were invited to participate. A history of postimmunization reactions, exposure to rubella, illness resembling rubella, and rubella revaccination was taken from the subjects or their parents.

Venous blood was collected and tested for rubella HI antibodies as previously described.[2,3] The follow-up serum sample (S_3) was analyzed simultaneously with the preimmunization (S_1) and postimmunization (S_2) samples from the same subject. The S_1 and S_2 sera collected in 1974 had been stored since then at −70 °C. Plaque-reducing neutralizing (Nt) antibody titers were performed in RK-13 cells according to a modification of the method of Fogel and Plotkin.[4] The HI and Nt titers are expressed as reciprocals of serum dilutions. This study was approved by the University of Minnesota Committee on the Use of Human Subjects in Research, and informed consent was obtained from the children or their parents before enrollment.

RESULTS

A total of 201 vaccinees participated in the four-year follow-up study. Their ages at the time of vaccination ranged from 1 to 17 years (median, 4.0 years; mean, 4.1 years). The median follow-up period was 4.1 years (mean, 4.2 years; range, 3.6 to 4.9 years), during which time none of the subjects had been revaccinated. The median age at the time of follow-up testing was 8.0 years (mean, 8.3 years; range, 4.9 to 20.9 years).

Two complications associated with vaccination were reported at the time of follow-up examination. In a 5-year-old boy who was seronegative prior to vaccination, arthritis of the left hip developed 31 days postimmunization. At the time of follow-up, his mother reported that he still experienced transient arthralgia, particularly on damp days, but his school attendance and physical activities were unimpaired. His hips were entirely normal on physical examination. In a boy who was 1 year of age and initially seronegative, a 1-cm macule developed at the vaccination site. The macule was first observed two weeks after vaccination and was still present four years later.

Only three of our vaccinees had any evidence of rubella reinfection during the follow-up period. Two girls who were seronegative and a boy who was seropositive before vaccination had fourfold or greater rises in HI titer between postimmunization (S_2 and S_3) samples. None of the three had a clinical illness that resembled rubella. The yearly incidence of rubella in Minnesota was relatively low during the period of follow-up. An average of

49 cases per year were reported to the Minnesota Department of Health between 1974 and 1978, with the fewest (18) observed in 1974 and the most (128) in 1978.

Of the 201 subjects studied, 186 had been seronegative and 15 had been seropositive before immunization (Table 1). In all of the seronegative subjects, rubella HI titers developed shortly after immunization, and thus there were no primary vaccine failures among this group. In the seropositive vaccinees, increased HI titers developed shortly after immunization, but these decreased to preimmunization levels when measured four years later. The geometric mean titers (GMTs) are displayed in Fig 1, which contrasts the effect of vaccinating seronegative and seropositive children. The rubella HI antibody responses for both groups were strikingly similar. Since there were only two postimmunization GMT values for each group, antibody titers seemed to decline steadily with time. Because that may not have been precisely the case, titers from seronegative subjects whose S_2 samples were collected 4, 8, 10, 12, or 14 weeks postvaccination were plotted separately (Fig 2). The points then represent different subjects, but the curve that connects them probably more accurately reflects the actual titer changes. The HI titers peaked eight to 12 weeks after immunization, had a somewhat rapid rate of decline shortly thereafter, and then leveled off (Fig 2). Children who were seronegative before vaccination had a GMT of 30.3, an arithmetic mean titer of 38.7, and a modal HI titer of 32 four years postimmunization.

Four (2.2%) of the 186 children who seroconverted after immunization had HI titers decline to less than 8 at the four-year examination (Table 2). These children would be considered secondary vaccine failures by HI testing. Plaque-reducing Nt titers were performed in addition to HI tests to characterize further their immune responses. In all four, HI and Nt titers developed immediately postimmunization. After four years, two subjects still had Nt antibodies, although HI titers had declined to undetectable levels.

Eleven vaccinees had HI titers of 8 at follow-up examination. Their sera also were tested for plaque-reducing Nt antibodies, and all had titers of 8 or greater. We could not evaluate the effect of passively transferred maternal antibody on durability of immuni-

Table 1.—Rubella Hemagglutination-Inhibiting (HI) Antibody Titers After RA27/3 Rubella Vaccine

Preimmunization Status*	Subjects Tested	Geometric Mean Titers			Postimmunization Titers < 8	
		S_1†	S_2‡	S_3§	S_2	S_3
Seronegative	186	0.0	74.0	30.3	0	4(2.2%)
Seropositive	15	36.8	84.4	35.1	0	0

*Seronegative indicates HI titer less than 8; seropositive, HI titer 8 or greater.
†S_1 indicates sera collected preimmunization.
‡S_2 indicates sera collected from 24 to 255 days postimmunization (median, 53 days).
§S_3 indicates sera collected from 3.6 to 4.9 years postimmunization (median, 4.1 years).

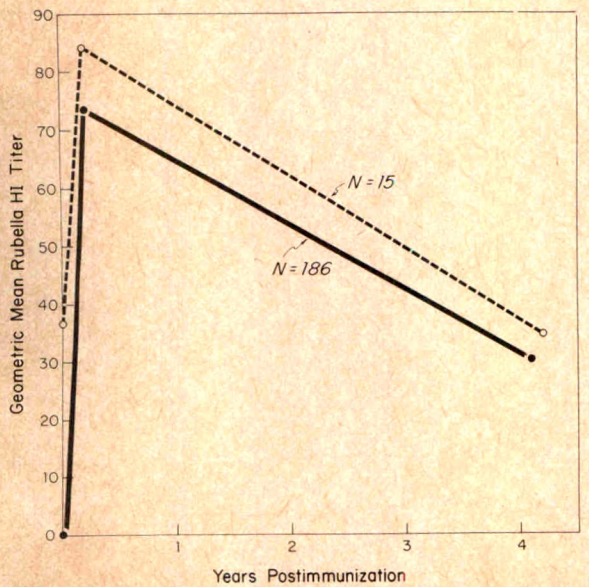

Fig 1.—Geometric mean rubella HI titers after RA27/3 immunization. Solid line shows results for 186 subjects seronegative before immunization. Dotted line represents 15 subjects seropositive before immunization.

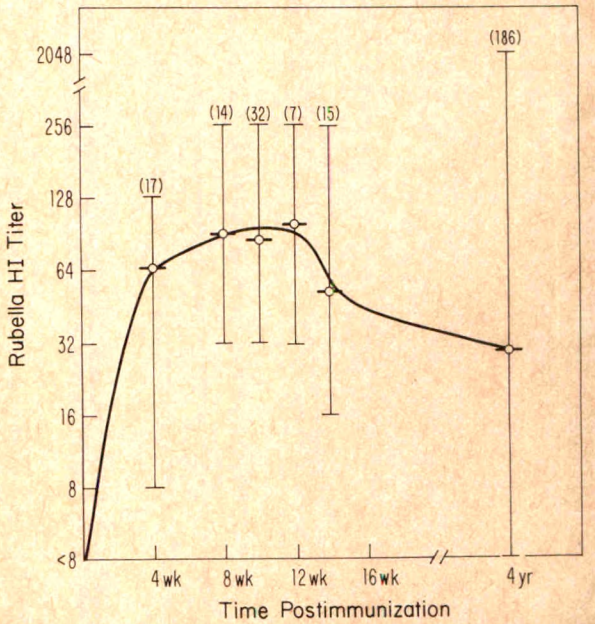

Fig 2.—Rubella HI titers induced by RA27/3 vaccine in children initially seronegative. Number of subjects at each time tested after immunization is given in parentheses. Ranges in HI titer for each point are indicated by horizontal lines. Curve is estimated by connecting geometric mean titers (indicated by circles).

Table 2.—Rubella Hemagglutination-Inhibiting (HI) and Neutralizing (Nt) Antibodies in RA27/3 Vaccinees Whose HI Titers Declined to Less Than 8 After Four Years

Sex	Age at Vaccination, yr/mo	S_1* Titers		S_2† Titers		S_3‡ Titers	
		HI	Nt	HI	Nt	HI	Nt
M	10/7	< 8	< 2	32	512	< 8	16
F	3/10	< 8	< 2	64	256	< 8	4
M	1/1	< 8	< 2	64	256	< 8	< 2
M	11/1	< 8	< 2	128	1,024	< 8	< 2

*S_1 indicates preimmunization sera.
†S_2 indicates sera collected 29 to 58 days (mean, 45 days) postimmunization.
‡S_3 indicates sera collected four years postimmunization.

ty after RA27/3 vaccination, because only eight children were immunized when 13 months of age or younger.

COMMENT

RA27/3 rubella vaccine induced durable immunity in the children studied with no primary vaccine failures, little evidence of reinfection, and a very low rate of secondary vaccine failure. At most, two (1.1%) of 186 initially seronegative vaccinees and one (6.7%) of 15 initially seropositive subjects had rubella reinfection during the four years postimmunization. Only four (2.2%) of 186 initially seronegative subjects demonstrated secondary serologic failure by HI testing, and two (1.1%) by Nt testing.

The reason for the loss of HI titers in four of our subjects is not readily apparent. Horstmann published data suggesting that children who mounted feeble HI responses to HPV77 DE5 rubella vaccine were most likely to lack HI titers at follow-up testing.[5] This was not true for our children who lost HI antibody, since they initially responded to RA27/3 vaccination with relatively high HI and Nt titers. Another possible reason for serologic failure is the age at immunization. Recently gathered data suggest that passively transferred maternal antibody may interfere with persistence of measles[2,6] and rubella[2] HI titers. However, passively transferred maternal antibody can be implicated in only one of our four vaccinees whose titer declined to an undetectable level, since the other three had been immunized when much older than 15 months. The vaccine could not have been inactivated by improper manufacture, transportation, or storage since it induced HI and Nt antibody titers shortly after immunization. Host immunologic responses, possibly genetically modulated, may be the reason for loss of titer with time in a few subjects. This possibility is intriguing, since histocompatibility antigens have been associated with susceptibility to rubella infection and rates of seropositivity in normal adult populations.[7] Fortunately, the present period of follow-up observation, as well as other studies, indicate that primary and secondary RA27/3 failures are uncommon. The overall RA27/3 serologic failure rate has been reported to be between 0% and 2.6%.[8-12]

The critical question not yet resolved is: do children, especially girls, who have no measurable antibody titer at follow-up testing need revaccination? RA27/3 vaccine can boost rubella HI titers. Fourfold or greater HI titer increases were found in 28 (23%) of 122 children who were seropositive before immunization in our 1974 RA27/3 field trial.[1] Since children with a history of rubella immunization were excluded from that study, those seropositive before immunization had antibody induced by natural infection. If RA27/3 vaccine can boost natural immunity, it should be able to boost vaccine-induced immunity as well. We have found in a preliminary study that RA27/3 vaccine given subcutaneously boosted HI titers in all ten children whose HI and Nt titers were undetectable four years after immunization with HPV77 DE5 rubella vaccine. Brandling-Bennett et al[13] have also demonstrated a booster effect of RA27/3 given either subcutaneously or intranasally. However, it is not clear that a booster immunization is needed because the level of antibody necessary to prevent rubella infection with viremia is not known. In the ten children whom we revaccinated, viremia could not be detected, but the number of samples and size of the group were small. Clearly, additional revaccination and challenge studies are needed to define the risk, if any, of wild rubella virus to a seronegative vaccinee. At present, it is reassuring that congenital rubella has not been reported in a term baby born to a woman appropriately vaccinated prior to pregnancy.

To our knowledge, the few follow-up reports available indicate that RA27/3 vaccine provides long-term immunity in children. Hillary and Freestone[8] demonstrated durable immunity for at least six years in 16 British children vaccinated between the ages of 15 months and 8 years. Buser[9] found that HI antibody titers persisted at least seven years in 15 Swiss children. Zourbas et al[14] found that HI titers were quite stable, persisting for at least five years in girls from Brittany who had been immunized at 11 to 13 years of age.

Rubella reinfections after RA27/3 immunization are uncommon. MacDonald et al[12] conducted a study six to eight years after immunization of women with RA27/3 vaccine or Cendehill vaccine. Reinfections were documented in only two of 196 women who received RA27/3 vaccine either subcutaneously or intranasally. In contrast, 14 (25.5%) of 55 women who had been given Cendehill vaccine had evidence of reinfection. Rubella reinfections, as indicated by fourfold or greater rises in titer between postimmunization samples, did not occur in the reports by Hillary and Freestone[8] or Buser.[9] Zourbas et al[10] did find evidence of reinfection after administration of RA27/3 vaccine, but the rate was not given. The reinfection rate in the present study was at most 1.5% (3/201). It might be as low as zero, because fourfold titer rises between postimmunization sera conceivably could be the result of delayed development of peak vaccine-induced titers. Since rubella infections, as reflected by cases reported to the Minnesota Department of Health, were not common during the follow-up peri-

od, the low rate of reinfection could be due to lack of exposure. Nevertheless, our findings combined with the other cited studies suggest that rubella reinfections are unusual in RA27/3 vaccinees.

Rubella reinfection certainly is undesirable if accompanied by viremia. However, subclinical wild rubella infection could be beneficial as a natural booster of immunity and may be responsible for persistence of rubella antibody titers in some vaccinees.

Three years after HPV77 DE5 immunization, Schluederberg et al found that Nt titers done in Vero cells were absent in three (21%) of 14 vaccinees with HI titers of 8 and in two of 14 with titers of 16.[15] Because of this finding and the possibility that Nt antibodies may correlate better with resistance to rubella reinfection than HI antibodies, we tested sera from all 11 vaccinees who had follow-up HI titers of 8. These 11 subjects had Nt titers of 8 or greater by a plaque-reducing method in RK-13 cell cultures. Thus, our subjects with low HI antibody titers did not lack Nt antibody. In fact, two of four children who lost HI antibody four years after RA27/3 had detectable Nt antibody.

Serologic failures in the present study were much less frequent than those found after HPV77 DE5 vaccination in a suburban Minneapolis pediatric practice (2.2% vs 36%).[2] The design of the HPV77 DE5 study, however, was different than the RA27/3 follow-up. RA27/3 vaccine had been administered in a field trial and was not given as a part of routine pediatric immunization. Second, sera from the HPV77 DE5 vaccinees were not collected in the immediate postimmunization period and thus we could not determine whether serologic failure was primary or secondary. Our data suggest that in HPV77 DE5 failures, antibody response either never developed or was very transient. A third difference was that only eight (4%) of 186 initially seronegative children were vaccinated with RA27/3 when younger than 14 months of age, whereas 80 (50%) of 159 were vaccinated with HPV77 DE5 when younger than 14 months old. The study of HPV77 DE5 vaccinees showed that age at time of immunization was important. Children vaccinated at 13 months of age or younger had a significantly higher serologic failure rate than those vaccinated at 14 months or older ($P < .005$). The high proportion of serologic failures after HPV77 DE5 therefore could be due in part to passive maternal antibody blunting the active immune response. Even taking into account these obvious differences, however, the conclusion that RA27/3 vaccine provided longer lasting serologic immunity than HPV77 DE5 seems justified.

Besides durable immunity, there are other advantages of RA27/3 vaccine. RA27/3 virus is grown in WI-38 human diploid fibroblast cells that have been exhaustively studied and seem to be free of infectious or oncogenic agents.[16] Also, qualitative and quantitative antibody responses induced by RA27/3 vaccine more closely resemble natural rubella than do those elicited by either Cendehill or HPV77 DE5 vaccines.[12,15,17]

Concern has been raised about risk to the fetus associated with RA27/3 vaccine.[18] However, there is evidence to support its lack of teratogenicity.[19] Since rubella immunization efforts are being aimed not only at preschool children, but at young women as well, and since RA27/3 is the only rubella vaccine now available in our country, much more information should be available shortly.

All things considered, we are fortunate that RA27/3 vaccine is now licensed and distributed in the United States. Available data indicate that it is safe and will provide both short- and long-term protection against rubella. Nevertheless, follow-up studies must continue, since vaccination of a 15-month-old girl requires at least 40 years of immunity to assure that none of her offspring will have congenital rubella.

This work was supported in part by a grant from the Wellcome Foundation.

Cameron Gundersen, MD, of the Gundersen Clinic, La Crosse, Wis, and LeRoy Norsted, PhD, of Independent School District 279, Osseo, Minn, assisted in collection of the serum samples.

Fulminant Neonatal Meningococcemia

Herbert W. Clegg, MD; I. David Todres, MD; Fergus M. B. Moylan, MD; Daniel E. Keim, MD; Daniel C. Shannon, MD

• ***Neisseria meningitidis*** **is a rare cause of infection in infants younger than 2 months of age, presumably because of transplacental passage of protective maternal antibodies. In most reported cases of meningococcal disease in neonates, a relatively mild clinical course has been observed. A 25-day-old infant survived acute, severe meningococcemia due to group B *N meningitidis*. This organism should be considered when neonates have signs of septicemia, especially in the presence of cutaneous petechiae and purpura.**

(*Am J Dis Child* 134:354-355, 1980)

Although *Neisseria meningitidis* is a well-known pathogen of infancy and childhood, it is not usually considered as being among those organisms causing infectious disease during the neonatal period.[1,2] In this report, we describe a healthy infant with fulminant meningococcemia to emphasize that this organism must be considered in the differential diagnosis of sepsis in the neonate.

REPORT OF A CASE

This 25-day-old male infant was referred to the emergency ward having vomited the previous evening, become febrile (39.6 °C), and irritable. His mother was a healthy woman whose term pregnancy, labor, and delivery were uncomplicated. The child's early neonatal course was unremarkable except for nasal congestion that had developed ten days prior to admission.

On arrival in the emergency ward, the infant's vital signs included a temperature of 39.6 °C rectally, a pulse rate of 210 beats per minute, an arm cuff blood pressure of 74 mm Hg (palpation), and respirations of 24/min. The extremities were mottled and cool; he appeared pale, toxic, and irritable. Small, macular, purplish lesions (<1 × 1 cm) were scattered over the thighs, anterior thorax, right axilla, and left shoulder. Results of the neurological examination were normal except for irritability, increased tone, and hyperactive, symmetrical reflexes throughout.

Initial laboratory data showed a WBC count of 3,600/cu mm with 12 polymorphonuclear leukocytes, 11 band forms, 72 lymphocytes, one myelocyte, three metamyelocytes, and zero eosinophils. The platelet count was 286,000/cu mm, and a capillary blood sample (patient in room air) showed a Po_2 of 52 mm Hg, a Pco_2 of 34 mm Hg, and a pH of 7.28. Normal studies included a chest roentgenogram and determinations for hemoglobin, prothrombin time (PT), partial thromboplastin time (PTT), serum electrolytes, BUN, osmolality, and calcium levels, and urinalysis. The blood glucose level was 66 mg/dL. Gram's stain of the buffy coat and CSF showed no bacteria, whereas material from a purpuric lesion contained polymorphonuclear leukocytes without organisms. The CSF had four WBCs per cubic millimeter (all lymphocytes) and 35 RBCs per cubic millimeter, with a glucose level of 49 mg/dL and protein concentration of 30 mg/dL. An ESR was not determined.

The admitting diagnosis was septicemia; and oxacillin sodium (200 mg/kg/day), gentamicin sulfate (7.5 mg/kg/day), and 5% albumin (10 mL/kg) therapy was administered. Several hours after admission, larger purpuric lesions were apparent on the face, trunk, and extremities. Meningococcemia was strongly suspected at this time. Ampicillin sodium was added to the regimen for broader coverage pending culture results; hydrocortisone was given (150 mg/kg then 150 mg/kg/day in four doses); elective intubation was performed; central venous and arterial lines were placed; and volume expansion using packed RBCs and plasma was undertaken. Isoproterenol hydrochloride therapy was begun for hypotension; and sodium bicarbonate, in addition to other fluids, was required for persistent metabolic acidosis (pH was as low as 7.15). A potassium infusion was also begun for hypokalemia (serum potassium levels decreased from 4.7 to 2.9 mEq/L seven hours after admission).

The platelet count decreased to 17,000/cu mm, with a PT greater than 18 s and PTT greater than 100 s. Gross hematuria and oozing of blood from cutdown sites developed. Therefore, in addition to receiving fresh frozen plasma, the baby underwent a 1½-volume exchange transfusion with fresh heparinized blood. One unit of platelets was given before and after the exchange transfusion.

Dopamine hydrochloride therapy was begun because of declining urine output and persistent hypotension present during the first 24 hours of admission (systolic pressure ranged from 42 mm Hg to values between 70 to 80 mm Hg on days 2 and 3). Anuria and azotemia ensued, and peritoneal dialysis was initiated. This was continued for six days until renal function returned.

On the fifth day, a grade 3/6 systolic murmer was first noted. The pulses were bounding, the central venous pressure increased to 20 mm Hg, and the liver span increased by 4 cm. A chest roentgenogram was compatible with pulmonary edema, and the clinical diagnosis of patent ductus arteriosus was suggested. Neither myocarditis nor pericarditis was suspected by clinical or ECG findings. Therapy included isoproterenol, more vigorous volume removal by peritoneal dialysis, and respiratory support. As diuresis continued during the following 48 hours, his condition improved noticeably. Extubation was accomplished on the 13th day at which time the cardiac murmur had disappeared and the chest roentgenogram had returned to normal.

The PT and PTT were normal by 3½ days, and the platelet count had reached 114,000/cu mm by seven days. Heparin sodium was not used therapeutically at any time, except during the exchange transfusion. Hepatomegaly with cholestasis was a prominent feature. The total serum bilirubin level peaked at 12.0 mg/dL on the third day and declined steadily to 3.5 mg/dL on the ninth day and to 1.0 mg/dL on the 16th day; the SGOT and serum alkaline phosphatase levels remained normal.

Neurologically, his course was complicated by seizure activity on the sixth day characterized by eyelid and twitching in the right leg and by staring episodes. After resolution of his metabolic abnormalities, an EEG on day 15 displayed considerable rhythmic activity for age but was otherwise normal (an EEG on day 6 had been diffusely abnormal).

Neisseria meningitidis, group B, sensitive to sulfadiazine, was identified in both sets of blood cultures and in the CSF; cultures of bladder urine, throat, and stool were negative. He received penicillin G (400,000 units/kg/day) to complete a ten-day course from the time of initiation of oxacillin therapy. Cultures of blood and CSF taken on the tenth day were negative, and the CSF at that time had ten WBCs per cubic millimeter (one mononuclear and

nine lymphocytes), zero RBCs, a protein level of 203 mg/dL, and a glucose level of 50 mg/dL.

Close contacts were identified and they along with the infant, the mother, and the father received rifampin prophylaxis; cultures were not taken of these individuals to determine their carriage status.

After his convalescence, the baby was discharged on a regimen of phenobarbital but was still hypotonic with poor visual pursuit. At 6 months of age, he was seen for repeated neurological evaluation. Two seizures had occurred since discharge, the last at age 3½ months. His developmental level was assessed as being 4 to 5 months of age. Moderate hypertonia of the upper extremities was noted, but vision seemed intact.

COMMENT

This infant experienced meningococcemia and meningitis with disseminated intravascular coagulation (DIC), leukopenia, probable acute tubular necrosis and renal failure, cardiac failure (probably secondary to a newly opened ductus arteriosus), and neurological dysfunction. That this constellation of initial problems gave him a grave prognosis was documented by Stiehm and Damrosch[3] in their retrospective study of 63 pediatric patients with meningococcemia. A very poor prognosis was associated with the presence of three or more of the five following features: the presence of petechiae for less than 12 hours prior to admission, the presence of shock (systolic blood pressure 70 mm Hg or less), a low or normal WBC count (< 10,000/cu mm), the absence of meningitis (WBCs < 20/cu mm in the CSF), and a low or normal sedimentation rate (< 10 mm/hr).

The early therapy provided for this infant was essentially that for Gram-negative sepsis with shock. Corticosteroids were used, but their use for the endotoxin shock associated with meningococcemia remains controversial.[4] He also received, in addition to other measures for DIC, an exchange transfusion and a therapeutic maneuver considered by some to be effective and safe for DIC in the neonate.[5]

Of interest was the hypokalemia. This has been observed in the first hours after admission in a group of 20 patients with meningococcemia, aged 9 months to 13 years, as a feature in those with hypotension (11 of 12 were hypokalemic, one not having had a potassium level measured). The remaining eight without hypotension did not have serial potassium measurements.[6]

To our knowledge, up to 1966, only 19 neonates with meningococcal disease had been described, and Stiehm and Damrosch[7] emphasized their comparatively benign course in their summary article. They discussed a 7-day-old infant that acquired group B meningococcal meningitis in the well-baby nursery, presumably from its mother's respiratory tract.[7]

To our knowledge, since 1966, only two other case reports of meningococcemia in the neonatal age group have appeared; both infants died. In the first case, a mother with meningococcal vaginitis may have transmitted the organism to her infant who died at 2 days of age with meningococcemia. Group C meningococci were recovered from the mother's lochia and pharynx and from the CSF and lung of the infant at postmortem examination.[8] Recently, a second case was reported in which fatal meningococcemia in a 15-day-old infant was associated with colonization of the maternal cervix.[9]

The incidence of disease has been shown to correlate with the absence of bactericidal antibodies to *N meningitidis*; more than 50% of the newborns have bactericidal titers of at least 1:4 against one or more test strains.[10] These antibodies would seem to be acquired transplacentally by those infants in whose mothers natural immunity had developed previously.[11] Placental transfer of antibodies to *N meningitidis* of groups A and C has recently been demonstrated, but antibody was not invariably found in infants of mothers who were immunized and seroconverted.[12]

The mode of acquisition of the organism in infected neonates is uncertain. Although two of the aforementioned cases suggest that intrapartum transmission via the maternal genitourinary tract might be important; genitourinary and anal carriage of *N meningitidis* in women is rare.[13,14]

It is clear from this case and the others cited that meningococcal disease does occur in neonates. Physicians caring for infants in this age group should consider this diagnostic possibility whenever cutaneous petechial or purpuric lesions are observed in a neonate.

Manginello et al[15] have very recently described a 2-week-old infant with meningococcemia and meningococcal meningitis who was successfully treated. They state that all close contacts should continue to be screened for respiratory and genitourinary colonization; but we should like to emphasize that close contacts be treated with an appropriate agent.

Metastatic Complications of *Fusobacterium necrophorum* Sepsis

Two Cases of Lemierre's Postanginal Septicemia

Lawrence C. Vogel, MD, Kenneth M. Boyer, MD

• **We have recently encountered two instances of septicemia due to *Fusobacterium necrophorum* in adolescents. The presence of severe exudative pharyngitis in both patients pointed to the upper respiratory tract as the probable portal of entry. In one case, metastatic infection was manifested by multiple septic pulmonary emboli with associated pleural effusions. In the other case, diffuse encephalopathy and septic arthritis of the left shoulder and hip occurred. Unilateral neck pain, persistent bacteremia, and prolonged fever despite appropriate antibiotics were consistent with the presence of septic jugular thrombophlebitis in both patients. "Postanginal septicemia" caused by *F necrophorum*, described by Lemierre in the preantibiotic era, was undoubtedly the syndrome manifested by these patients. This condition, formerly uniformly fatal, can readily be diagnosed when anaerobic techniques are used for blood culture, but requires prolonged antibiotic therapy for cure.**

(*Am J Dis Child* 134:356-358, 1980)

Although anaerobic Gram-negative bacilli of the family Bacteroidaceae are increasingly being recognized in septicemic illnesses,[1-4] the pathogenic potential of these organisms was well known in the preantibiotic era. A clinical entity known as "postanginal septicemia" in which oropharyngeal infection is complicated by local septic thrombophlebitis, continuous anaerobic bacteremia, and multiple sites of metastatic infection was summarized in 1936 by Lemierre,[5] "The appearance and repetition several days after the onset of a sore throat... of severe pyrexial attacks with an initial rigor, or still more certainly the occurrence of pulmonary infarcts and arthritic manifestations, constitute a syndrome so characteristic that mistake is almost impossible."

The most frequent causal agent in this syndrome, known to Lemierre[5] as *Bacillus funduliformis*, is now classified as *Fusobacterium necrophorum*. We have recently cared for two adolescent patients with anaerobic sepsis due to this organism. Their clinical features were remarkably similar to Lemierre's early description of postanginal sepsis. Despite appropriate antibiotic therapy, both patients had dramatic and prolonged febrile illnesses associated with persistent bacteremia and metastatic spread of infection.

REPORT OF CASES

CASE 1.—A 16-year-old girl was hospitalized with a three-day history of sore throat, unilateral neck pain, and dysphagia, and two days of fever and vomiting. On admission, she was lethargic and appeared acutely ill. Her temperature was 38.6 °C. Her left tonsil was enlarged and covered by gray exudate. The left side of her neck, along the anterior border of the sternocleidomastoid muscle, was tender and swollen.

Laboratory values were as follows: hemoglobin, 12.5 g/dL; hematocrit, 38.2%; and peripheral WBCs, 11,100/cu mm, with 65% polymorphonuclear leukocytes, 25% band forms, 4% lymphocytes, 5% monocytes, and 1% eosinophils. Urinalysis showed moderate proteinuria. The urinary sediment contained 60 to 70 WBCs per high-power field (HPF). Chest and lateral neck roentgenograms were normal.

After admission, she continued to have sore throat, high temperatures up to 40 °C, and intermittent shaking chills. Throat cultures were negative for group A β-hemolytic streptococci. Urine cultures were sterile. No serum heterophile antibody was detectable. On the third hospital day, Gram-negative bacilli were observed in the thioglycollate broth of the admission blood culture. Therapy with intravenous cephalothin sodium succinate (170 mg/kg/day), gentamicin sulfate (5 mg/kg/day), and chloramphenicol (85 mg/kg/day) was begun. On the fifth hospital day, the bacilli were identified as obligate anaerobes, and therapy was changed to intravenous penicillin G potassium (250,000 units/kg/day). A chest roentgenogram on the fifth hospital day showed bibasilar infiltrates and pleural effusions. A right thoracentesis yielded serous fluid that was negative by Gram's stain and sterile on aerobic and anaerobic culture. The fluid contained 3,300 WBCs per cubic millimeter (all polymorphonuclear leukocytes) and had a specific gravity of 1.026 and total protein content of 4.1 g/dL. Spiking fever persisted for the first ten hospital days and then gradually defervesced during the next eight days. Serial chest roentgenograms demonstrated resolution of the pleural effusions and development of multiple pneumatoceles (Fig 1). She received a total of 25 days of therapy with intravenous penicillin G, followed by an additional three months of therapy with oral penicillin V. During this time, the pneumatoceles completely resolved.

The anaerobic organism present in each of the five blood cultures obtained during her first four days of hospitalization was identified as *F necrophorum*.[6] Anaerobic broth dilution susceptibility testing of the isolate to penicillin G, using thioglycollate broth supplemented with 10% horse serum, demonstrated minimal inhibitory and bactericidal concentrations of 0.04 μg/mL.[7]

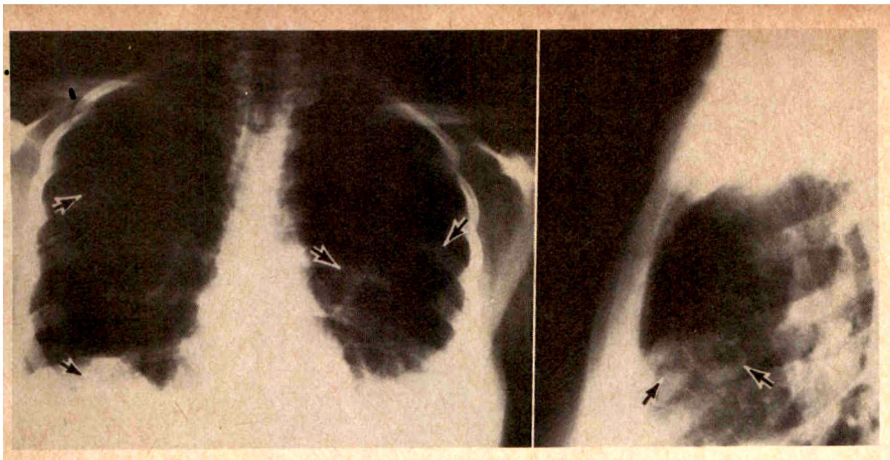

Fig 1.—Chest roentgenogram of case 1 obtained on 13th day of illness. Pneumatoceles are present in both lung fields.

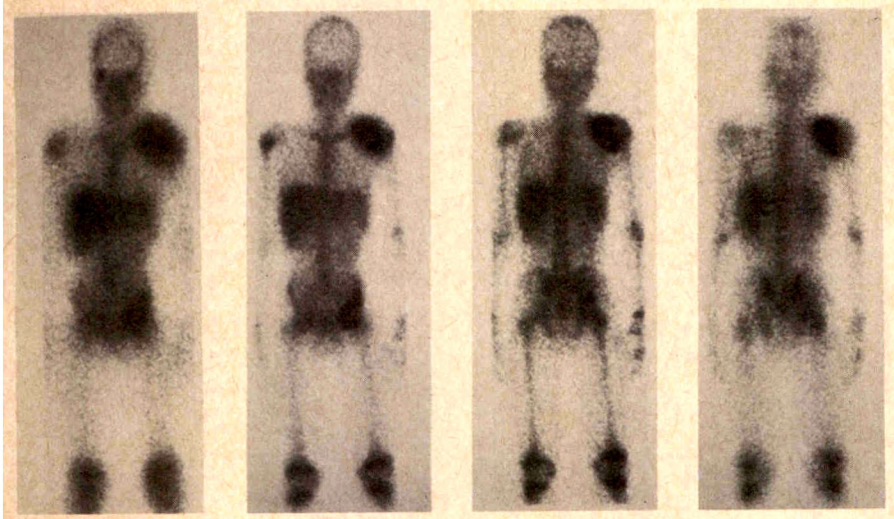

Fig 2.—Tomographic gallium 67 scans of case 2 obtained on tenth day of illness. Increased radionuclide uptake is evident in left shoulder and hip joints.

CASE 2.—A 12-year-old boy was hospitalized with a five-day history of sore throat, three days of fever and lethargy, and one day of diplopia and pain in the left knee, shoulder, and neck. On admission, he was lethargic and disoriented. His temperature was 39.5 °C. Both tonsils were erythematous with gray membranes, and the left side of his neck was tender. The liver was enlarged to 5 cm below the right costal margin. The left knee, hip, and shoulder were tender, with limitation of motion but without palpable joint effusions. Neurologic examination disclosed an attentional defect, hallucinations, and dysconjugate gaze consistent with a diffuse encephalopathy.

Laboratory findings were as follows: hemoglobin, 12.4 g/dL; hematocrit, 38%; and WBCs, 9,200/cu mm, with 45% polymorphonuclear leukocytes, 32% band forms, 5% metamyelocytes, 14% lymphocytes, and 4% monocytes. The urinary sediment contained 20 to 30 RBCs and four to six WBCs per HPF. Cerebrospinal fluid was clear and colorless with no cells, glucose level was 92 mg/dL, and protein concentration was 15 mg/dL. The Westergren ESR was 125 mm/hr. Throat cultures were negative for group A β-hemolytic streptococci, although serum antistreptolysin O and antihyaluronidase titers were 1:640 and 1:512, respectively. Serum heterophile antibody titers were negative. A brain scan and roentgenograms of the chest, skull, neck, left leg, and left shoulder were normal. An EEG demonstrated diffuse slowing.

Intravenous penicillin G potassium therapy (100,000 units/kg/day) was started on admission. Lethargy and high temperatures to 41 °C persisted. On the third hospital day, Gram-negative filamentous bacilli were isolated from the thioglycollate broth of the admission blood culture. Intravenous therapy with ampicillin sodium (300 mg/kg/day), gentamicin sulfate (5 mg/kg/day), and chloramphenicol sodium succinate (60 mg/kg/day) was begun. When the blood culture isolate proved to be an obligate anaerobe, therapy was changed to penicillin G potassium (300,000 units/kg/day) and chloramphenicol sodium succinate (100 mg/kg/day). High fever persisted for the first ten hospital days, but steady improvement in sensorium and neurologic findings occurred. Radionuclide scans with gallium 67 showed increased uptake in the left shoulder and iliac bone (Fig 2); technetium 99 pyrophosphate scans confirmed the presence of inflammatory lesions of the left shoulder, hip, and knee. With clinical improvement and in the absence of effusions of the involved joints, arthrocentesis was deferred. A total of three weeks of intravenous penicillin G and chloramphenicol therapy was given, followed by an additional two months of oral penicillin V therapy. All symptoms resolved completely.

The anaerobic isolates from blood cultures obtained on the first, third, and fourth hospital days were identified as *F necrophorum*. By anaerobic disk techniques, the organism proved to be sensitive to both penicillin and chloramphenicol.[7] Anaerobic broth dilution susceptibility testing to penicillin G showed a minimal inhibitory concentration of 0.08 μg/mL and minimal bactericidal concentration of 0.15 μg/mL.

COMMENT

Fusobacteria are obligately anaerobic, nonsporulating, Gram-negative bacilli of the family Bacteroidaceae. Their characteristic fusiform morphology is distinctive, but modern techniques of speciation are based on identification of specific volatile fatty acid metabolic by-products by gas-liquid chromatography.[6] Fusobacteria are major contributors to the normal flora of the oral cavity, the female genital tract, and, to a lesser extent, the gastrointestinal tract. With *Treponema vincentii*, they were classically described in localized "fusospirochetal" infections of the oral cavity, such as Vincent's angina ("false diphtheria") and Vincent's stomatitis ("trench mouth"). When modern anaerobic techniques have been used for diagnosis, they have been frequently isolated from dental abscesses, peritonsillar abscesses, aspiration pneumonias, and lung abscesses, and, less commonly, from appendiceal abscesses, liver abscesses, and tuboovarian abscesses.[8]

Of the 17 known species of *Fusobacterium*, *F necrophorum* and *F nucleatum* have been most frequently recovered in anaerobic sepsis. Although numerous descriptions of serious infections caused by *F necrophorum* appear in the literature of the preantibiotic era, bacteriologic uncertainty exists regarding many of these cases

because of varying criteria for speciation of isolates. Some 52 synonyms and probable synonyms for this species, of which *Sphaerophorus necrophorus*, *B funduliformis*, and *Fusiformis necrophorus* are encountered frequently, add to the difficulty of interpreting this early work.[8]

In a recent prospective survey of anaerobic infections in pediatric patients, Dunkle et al[9] encountered 41 instances of anaerobic bacteremia, of which three were due to fusobacteria (all *F nucleatum*). In a similar study, Thirumoorthi et al[10] found 34 instances of anaerobic bacteremia, of which two were due to fusobacteria (one *F glutinosum*, one not speciated). The nature of these fusobacterial septicemias was not further specified. Several case reports of septic illness from which fusobacteria were recovered have also appeared in the pediatric literature in recent years. Oleske et al[11] described a 14-year-old boy with pharyngitis, peritonsillar abscess formation, and multiple lung abscesses. *Fusobacterium necrophorum* was isolated from the neck mass in pure culture, although multiple blood cultures were negative.

Rubenstein et al[12] described a 7-year-old boy in whom unilateral cervical mass, pericarditis, and *F gonidiaformans* bacteremia developed after tonsillectomy and adenoidectomy. Two patients with anaerobic meningitis and bacteremia caused by fusobacteria (one *F gonidiaformans* and one not speciated) were described by O'Grady and Ralph.[13] In one of their cases, otitis media and acute mastoiditis were the probable source of bacteremia. In the other, exudative pharyngitis was a prominent associated finding. All four of these patients had prompt therapeutic responses to appropriate antibiotics. However, in three instances relapses occurred after short initial courses of therapy.

Our case 1 had febrile illness characterized by exudative tonsillitis, unilateral neck pain, vomiting, and sterile pyuria. Multiple septic pulmonary emboli developed during hospitalization. *Fusobacterium necrophorum* bacteremia persisted for four days, despite the initiation of appropriate antibiotic therapy. Although the infecting organism was shown to be quite sensitive to penicillin G, the patient's hospital course was prolonged, and recovery was gradual.

Case 2 also had multisystem involvement when first seen, with conspicuous CNS and skeletal system involvement tending to overshadow the presence of exudative pharyngitis. *Fusobacterium necrophorum* bacteremia also persisted for four days, despite therapy with intravenous penicillin G and chloramphenicol, to which the isolate was subsequently proved to be sensitive. Chloramphenicol was used in the regimen based on the patient's neurologic involvement and pending the results of definitive antibiotic susceptibility testing. The patient's encephalopathy cleared during the first week after initiation of therapy, but joint symptoms continued until shortly before discharge in the fifth week of illness.

In both cases, the findings of exudative pharyngotonsillitis, unilateral neck pain and swelling, persistent bacteremia, and embolic phenomena were consistent with the presence of septic thrombophlebitis of the tonsillar and internal jugular veins. In the cases reported by Lemierre,[5] this finding was uniformly present at autopsy and was considered by him to be central in the pathogenesis of the condition.

The slow therapeutic response to appropriate antibiotics in our two patients was particularly worrisome. Fusobacteria, as a rule, are quite sensitive to penicillins, chloramphenicol, clindamycin, and metronidazole.[14] Our cases were not exceptional. In fact, during treatment of case 2, peak serum bacteristatic activity was present in a dilution of 1:1,024. It is probable that the prolonged febrile courses we observed were related to the presence of metastatic suppurative foci secondary to septic thrombophlebitis. These foci were not readily amenable to surgical drainage. In a similar situation, Josey and Staggers[15] observed rapid clinical improvement in 42 of 46 cases of septic pelvic thrombophlebitis, 15 of which had concomitant metastatic pulmonary infection, when heparin sodium was added to appropriate antibiotic regimens. No controlled trials are available, however, that establish the value of this adjunctive therapy. In retrospect, the use of heparin would probably have been appropriate in our case 1; in case 2, the predominant neurologic involvement made us hesitate to use anticoagulant drugs.

The distinctive syndrome of "postanginal sepsis" due to *F necrophorum* should be borne in mind by the clinician faced with septic illness complicating oropharyngeal infection. Prolonged antibiotic therapy seems to be necessary for eradication of these serious anaerobic infections.

William L. Schey, MD, and V. Yun Ryo, MD, gave permission to reproduce the roentgenograms. Earnestine Cloyd, MS, performed the anaerobic susceptibility testing. Madeline Murphy provided secretarial assistance.

Spectinomycin Therapy for Gonorrhea in Prepubertal Children

Philip J. Rettig, MD; John D. Nelson, MD; Helen Kusmiesz, RN

• **Twenty-six episodes of gonococcal urethritis or vulvovaginitis in 24 prepubertal patients were each treated with a single intramuscular (IM) dose of spectinomycin hydrochloride. Twenty-five episodes were treated successfully, and there were no side effects from this therapy. All tested isolates of *Neisseria gonorrhoeae* were susceptible in vitro to spectinomycin, and all serum levels one hour after therapy were in at least two-fold excess of the observed minimum inhibitory concentrations. Two patients had symptomatic and two had asymptomatic postgonococcal anogenital infections with *Chlamydia trachomatis*. A single dose of IM spectinomycin is a safe and efficacious regimen for uncomplicated gonococcal infection in prepubertal children who are penicillin-allergic or who have infections unresponsive or resistant to other antimicrobials, but it is not effective against incubating syphilis or chlamydial infection.**

(*Am J Dis Child* 134:359-363, 1980)

The recognition of penicillinase-producing *Neisseria gonorrhoeae* (PPNG) in 1976[1] and subsequent worldwide dissemination of these strains[2] have added urgency to the search for safe and effective alternatives to penicillin G and other β-lactamase-susceptible antibiotics for the therapy of gonococcal infections. As of March 1979, PPNG strains had been reported in 27 countries and in 31 states.[2] They have been associated with a wide spectrum of clinical manifestations, including one case report of vulvovaginitis in a prepubertal girl.[3]

The most recent Public Health Service recommendations for treatment of uncomplicated gonorrhea in adults suggest the use of spectinomycin hydrochloride for penicillin-allergic patients who are also intolerant of tetracycline hydrochloride, for all patients who fail to respond to initial therapy with a penicillin or tetracycline, and for all PPNG-infected patients and their sexual contacts.[4] Spectinomycin has been extensively studied in adults during the past 17 years, initially as the sulfate salt (actinospectocin) and subsequently as the currently available dihydrochloride pentahydrate salt. It has been a well-tolerated and effective drug for uncomplicated anogenital gonorrhea.[5-13] To our knowledge, there is no information on the use of spectinomycin in pediatric patients with gonococcal infections except for the one case previously mentioned.[3] The purpose of this study was to evaluate the efficacy of spectinomycin hydrochloride in uncomplicated gonorrhea in children.

SUBJECTS AND METHODS

Patient Selection

Eligible patients were those between 1 and 15 years of age who were initially evaluated for urethritis or vulvovaginitis, thought to be gonococcal on clinical and bacteriologic grounds. Patients were initially seen in the ambulatory care clinic at the Children's Medical Center or in the pediatric emergency room at Parkland Memorial Hospital in Dallas. Entry into the study was based on demonstration of abundant, Gram-negative, intracellular diplococci in genital secretions or cultural confirmation of *N gonorrhoeae* if Gram-stained specimens were not diagnostic. Children were scheduled for two follow-up visits at four to six days and ten to fourteen days for repeated physical examinations and test-of-cure cultures. Written informed consent for entry into the study and for spectinomycin treatment was obtained from the parents. The patients and attending parents were interviewed by a pediatric social worker and were reported to the Dallas City Health Department venereal disease control clinic.

Laboratory Procedures

Anal, pharyngeal, and genital swabs were collected at each visit and inoculated onto blood agar, chocolate agar, and modified Thayer-Martin agar containing vanco-

From the Department of Pediatrics, University of Texas Southwestern Medical School at Dallas. Dr Rettig is now at Children's Memorial Hospital, University of Oklahoma Health Sciences Center, Oklahoma City.

Reprints not available.

mycin, colistin, and nystatin. Vaginal and anal cultures were also inoculated onto eosin-methylene blue agar. Thayer-Martin and chocolate agar plates were incubated in candle extinction jars. Isolation of *N gonorrhoeae* was confirmed by growth of Gram-negative diplococci that fermented dextrose and failed to ferment sucrose or maltose in cystine trypticase agar. Genital, anal, and pharyngeal swabs were also placed in sucrose-phosphate buffer containing gentamicin and amphotericin B and frozen at −70 °C for chlamydial cultures. *Chlamydia trachomatis* isolation was made in 5-iodo-2-deoxyuridine-treated McCoy cells by the method of Wentworth and Alexander.[14]

Serologic tests for syphilis (VDRL) were obtained at the initial treatment visit and were repeated between two and three months after therapy.

Susceptibility testing was done by agar dilution using penicillin G and spectinomycin laboratory standards. Loopfuls of an overnight growth on chocolate agar were suspended in 1.0 mL of Mueller-Hinton broth with 1% of a broth supplement (IsoVitaleX) to a turbidity approximating 10^9 organisms per milliliter. A final dilution of 10^4 to 10^5 colony-forming units per milliliter was plated on chocolate agar (GC agar base with 2% hemoglobin and 1% IsoVitaleX) containing two-fold dilutions of the antibiotics tested. Inhibitory end points were read after 24 hours' incubation at 36 °C in candle extinction jars. In addition, disk diffusion sensitivities using 100-μg spectinomycin disks were performed using a modified Kirby-Bauer method, with the previously mentioned inoculum and medium. Isolates from treatment failures and those showing decreased penicillin sensitivity (minimal inhibitory concentration [MIC] ≥ 1.25 μg/mL) were tested for β-lactamase activity using a rapid iodometric paper strip test.[15]

Serum specimens were obtained from patients one hour after injection of spectinomycin. Antibiotic levels were determined by a standardized plate microbioassay using *Escherichia coli*.

Treatment

Patients received a single dose of 40 mg/kg of spectinomycin hydrochloride injected intramuscularly into the buttock or anterolateral thigh. Volumes greater than 3.0 mL were divided and administered in two injection sites.

RESULTS

Between February 1978 and November 1978, 26 episodes of gonococcal urethritis or vulvovaginitis in 24 patients were treated. All patients were prepubertal (defined as absence of breast development in girls and testicular length <4 cm in boys). One 7-year-old boy had three episodes of gonococcal urethritis during a 4½ month period. Ages ranged from 2 years, 4 months to 12 years, 11 months, with an average of 7 years. The mean age of female patients (67 months) was significantly less than that of male patients (102 months) ($P < .01$; Student's t test, $t = 2.61$; $df = 24$).

All patients were symptomatic, with the most common symptom being a genital discharge (present in all 26 episodes). In the boys, 11 of 13 episodes were accompanied by dysuria. One boy had balanitis and four had erythema and edema of the urethral meatus. Six female patients had complaints of dysuria, and three others had urgency or increased frequency of urination. Two had lower abdominal pain by history, but neither had adnexal tenderness or masses. Abnormal physical findings in girls were limited to vaginal discharges (13 of 13 patients), which ranged from white and mucousy to thick, green, and malodorous, and to vulvar and introital erythemas (nine of 13). In eight episodes, patients had been symptomatic for only one day; and in 19 (73%), symptoms had been present for one week or less. Two female patients had discharges for three and for four weeks before treatment.

Smears of genital discharges were initially positive in all 26 episodes. Genital cultures confirmed *N gonorrhoeae* infection in 23 instances. In three cases, Gram-negative diplococci were isolated in pure growth on Thayer-Martin media, but they could not be confirmed as *N gonorrhoeae* by carbohydrate fermentations because of technical problems. Two of these patients were siblings of a third child (not in this study) who had had confirmed gonococcal urethritis one week earlier. All three were believed to have gonococcal infection on the basis of clinical characteristics, Gram's-stain findings, epidemiologic features, and clinical responses. None of 22 pretreatment rectal cultures were positive for the gonococcus. *Neisseria gonorrhoeae* was isolated from the pharyngeal culture of a 6-year, 11-month-old girl, but the remaining 21 throat cultures were negative. No patient initially had a reactive VDRL test, and follow-up serologic tests obtained from 14 patients remained nonreactive.

At least one follow-up evaluation was made in each patient. A total of 24 patients had cessation of symptoms within 96 hours of therapy, including 20 who were symptom-free within 48 hours. Two patients, one boy and one girl, had continued purulent genital discharge when seen at follow-up six and four days, respectively, after therapy. The 7-year-old boy had repeated urethral smear and culture positive for *N gonorrhoeae*. His organism had an MIC to spectinomycin of 20 μg/mL both before and after treatment and was β-lactamase-negative. The serum level of spectinomycin one hour after injection was assayed as 62 μg/mL. He responded clinically and bacteriologically to oral tetracycline hydrochloride, 40 mg/kg/day for four days. He denied reexposure and was considered the only treatment failure. However, he subsequently had two more episodes of gonococcal urethritis successfully treated with spectinomycin, and it is possible that his earlier "failure" was actually due to reinfection. All remaining patients were bacteriologically negative at the first (25/25) and second (23/23) follow-up examinations.

The 7-year-old girl with persistent nongonococcal vaginal discharge had positive rectal and vaginal cultures for *C trachomatis*. Her symptoms and positive chlamydial cultures continued for two weeks until her condition was treated with oral trisulfapyrimidines (120 mg/kg/day for ten days). An additional case of symptomatic postgonococcal genital infection owing to *C trachomatis* occurred in a 7-year-old boy who had recurrence of a thin, watery, urethral discharge 12 days after spectinomycin therapy. Two additional patients had asymptomatic postgonococcal chlamydial infection of the rectum and of the rectum and vagina.[16]

Minimal inhibitory concentrations of penicillin G and spectinomycin in 24

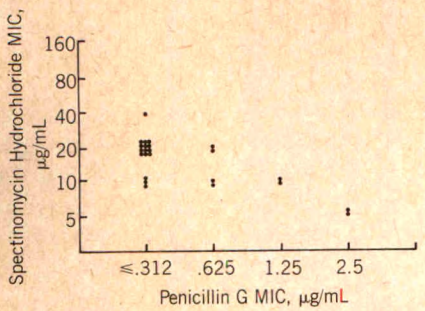

Fig 1.—Minimal inhibitory concentrations (MICs) of spectinomycin hydrochloride and penicillin G against *Neisseria gonorrhoeae* by agar dilution.

gonococcal isolates are shown in Fig 1. No isolates were β-lactamase-positive. Of the isolates, 87% had spectinomycin MICs of 10 or 20 µg/mL, with the median MIC being 20 µg/mL. There was no apparent direct or inverse correlation between penicillin and spectinomycin sensitivities.

The correlation between the disk zone of inhibition and the MIC for spectinomycin is shown in Fig 2. The line of regression was calculated by the method of least squares, expressing the MICs as relative values on the Y-axis (correlation coefficient was $-.458$, $.01 < P < .05$).

Serum levels of spectinomycin hydrochloride one hour after intramuscular (IM) injection of 40 mg/kg ranged from 22 µg/mL to 87.5 µg/mL. The arithmetic mean level was 64.3 ± 3.8 µg/mL (arithmetic mean ± SEM) and the median value was 72 µg/mL. Serial blood samples were available from three patients, and the results are shown in Fig 3. The drug was well tolerated in all patients, and no local or systemic side effects were reported.

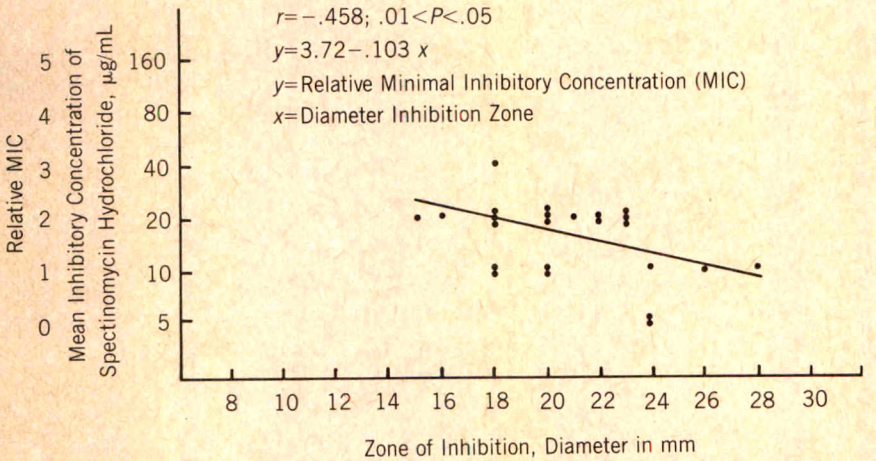

Fig 2.—Correlation of spectinomycin hydrochloride susceptibilities of *Neisseria gonorrhoeae* as determined by agar dilution and disk diffusion.

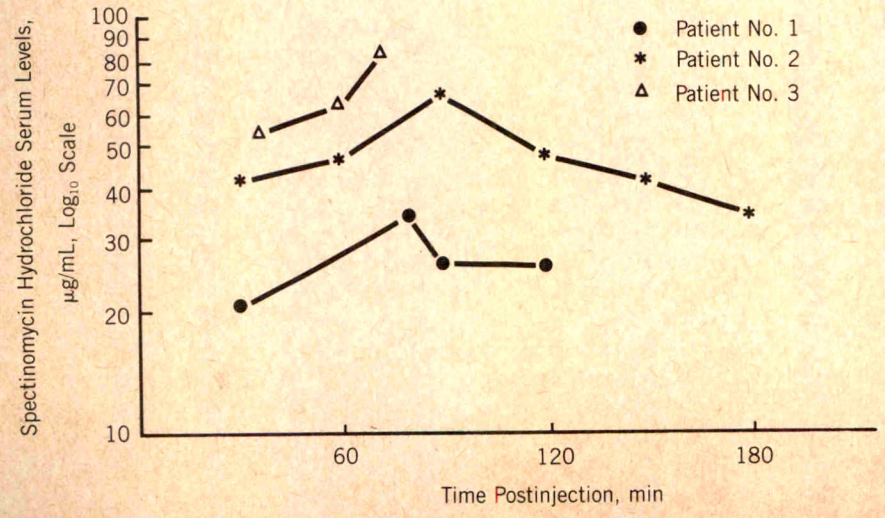

Fig 3.—Serial spectinomycin hydrochloride serum levels after 40 mg/kg intramuscular injection.

COMMENT

The cure rate (96.1%) in this series of pediatric patients is comparable with those previously reported in adults with anogenital infection.[5-13] The drug has had minimal toxic effects in adults and was uniformly well tolerated by subjects in this study. Although there were no PPNG isolates from patients in this study, several recent reports have shown spectinomycin to be curative against such strains,with success rates comparable with those seen with β-lactamase-negative isolates.[3,17,18]

The epidemiologic and clinical characteristics of this group of patients were similar to those previously reported from our hospitals.[19] The significantly different ($P < .01$) average ages between male and female patients were observed in the earlier study, and they may in part be due to the observation by Branch and Paxton[20] that children aged 2 to 9 years were most often exposed to infection by molestation within the family while children 10 years or older were most often infected by voluntary heterosexual activity. However, definite information concerning the source of infection was lacking in the majority of our patients, and this hypothesis cannot be confirmed. The previous treatment study showed high rates of anal (40%) and pharyngeal (17%) coinfection in pretreatment cultures. Only one patient in this series had pharyngeal gonococcal infection, and all anal cultures were negative for *N gonorrhoeae*. After the conclusion of this study, it was realized that the anal cultures were in fact rectal

cultures, owing to deeper insertion of cotton swabs, ie, beyond the anal crypts. This may explain the negative yield from this site because in all other respects, the patient populations were similar and the microbiologic methods identical in the two studies.

The range of in vitro susceptibilities of gonococci to spectinomycin in this study is somewhat higher than that noted by some previous investigators[6-8,10,12,21,22]; but it is similar to that in other studies,[9,13] in our previous study,[19] and in the Center for Disease Control National Gonorrhea Therapy Monitoring Study.[22] These discrepancies between studies may be due to the use of different antibiotic dilutions and to difficulties in standardizing inocula rather than to any true geographic or temporal susceptibility differences. Although some investigators have found a weakly positive correlation between penicillin and spectinomycin susceptibilities,[7,9,11,12] not all studies have shown such an association,[8] and none was evident in this study. Although PPNG isolates from the United States were relatively less susceptible to spectinomycin than non-PPNG strains, all had spectinomycin sensitivities ≤ 16 μg/mL.[18] No decreased spectinomycin susceptibility in PPNG isolates from the Far East compared with β-lactamase-negative Asian isolates was noted by Thornsberry et al.[23] Most importantly, there has been no association between increased treatment failure rates with spectinomycin and decreased penicillin sensitivity.[22]

Spectinomycin treatment failures have not been correlated with increasing in vitro resistance to the drug. Our one treatment failure had adequate serum levels of the antibiotic and was infected with an organism demonstrating in vitro sensitivities before and after therapy (MIC, 20 μg/mL). Although there have been three reported spectinomycin-resistant *N gonorrhoeae* isolates from clinical specimens[24,25] and high-level resistance is readily inducible in vitro, most treatment failures with this drug are due to an unknown mechanism and not to demonstrable intrinsic resistance.[12,22]

The occurrence of postgonococcal infections with *C trachomatis* has been noted in spectinomycin treatment studies in adults, with incidence rates from 7% to 27%.[5,22,26,27] Spectinomycin has no in vitro activity against *C trachomatis* at usually attainable serum concentrations. This fact, along with the drug's lack of efficacy against incubating syphilis, is one of its main disadvantages as a first-line drug for all uncomplicated gonococcal infections.

Disk agar-diffusion sensitivities of *N gonorrhoeae* have been performed infrequently because of the organism's slow, somewhat fastidious growth and because of the difficulty in standardizing inoculum size. The results obtained in this study are consistent with those obtained by Washington and Yu[28] when they examined disk sensitivities of coliform bacteria to spectinomycin. All isolates in our study had zone diameters greater than 14 mm, which concurs with the suggestion by Washington and Yu that zone diameters of less than 14 mm with a 100-μg spectinomycin disk be interpreted as showing resistance. The rather low correlation coefficient (−.458) may be due to the narrow range of spectinomycin susceptibilities and the small number of strains tested. Although Washington and co-worker's suggested interpretive zone diameters may be applicable to gonococcal sensitivities, it would be advisable to test for gonococcal spectinomycin susceptibility by more established agar dilution methods until larger numbers of isolates are examined in a well-standardized and highly reproducible fashion.

The serum spectinomycin levels in our patients were lower than those reported in adults after a single IM injection of 2.0 g.[26,29] (The 40 mg/kg dose used in our study would give a larger dose, on a weight basis, to a 70-kg adult than the commonly used 2.0-g dose). Brownlow et al[26] found an average serum concentration of 88.6 ± 33.9 μg/mL (mean ± SD) two hours after a single 2.0-g IM injection of the hydrochloride salt. An average level of 109.2 μg/mL was obtained in 12 adult volunteers one hour after injection (The Upjohn Company, unpublished data). In pediatric patients, Barry and Koch[30] reported one-hour serum levels of 60 and 80 μg/mL in two patients given 25 mg/kg of the sulfate salt intramuscularly, and an average of 30 mg/kg in five patients given 12.5 mg/kg. The serial serum levels from three of our patients (Fig 3) suggest that peak serum concentrations may have occurred later than one hour after injection. Despite the somewhat lower-than-expected levels observed in this study, the mean level at one hour was fourfold greater than the average MIC.

Spectinomycin has not been evaluated in extragenital or disseminated gonococcal infection in children. It has not been effective in oropharyngeal gonorrhea in adults.[13] There are no data on this drug's pharmacokinetics or toxicity in neonates, and its use in newborns cannot be recommended. Clinicians treating pediatric gonorrhea should restrict the use of spectinomycin to those clinical situations outlined in the published guidelines, and they should be aware that spectinomycin does not eradicate incubating syphilis and is not effective against concurrent infections with *C trachomatis*. Our study does support the recent PHS-recommended dose of 40 mg/kg for uncomplicated pediatric anogenital gonococcal infection. The therapeutic efficacy, safety, and in vitro gonococcal susceptibility patterns of spectinomycin in this series of pediatric patients are similar to results obtained previously in adults.[31]

This study was supported by a grant from The Upjohn Co, Kalamazoo, Mich.

Edythe Woodman performed the antimicrobial susceptibility testing, Sharon Shelton performed the antibiotic assays, and Kathy Faust performed the cultures for *Chlamydia*.

CORRECTION

Order of Authors' Names in Signature Incorrect.—In the article titled "Craniosynostosis-Radial Aplasia: Baller-Gerold Syndrome," published in the December JOURNAL (133:1279-1280, 1979) the order of the authors' names in the signature was incorrect. The order of the authors' names should be as follows: Susan L. Sklower, MD, Judith P. Willner, MD, M. Michael Cohen, DMD, Murray Feingold, MD, Robert J. Desnick, PhD, MD.

The Role of Respiratory Infection in Intrathoracic Petechiae

Implications for Sudden Infant Death

Warren G. Guntheroth, MD; Isamu Kawabori, MD; Donald G. Breazeale; Leland E. Garlinghouse, Jr, MS; Gerald L. Van Hoosier, Jr, DVM

• Intrathoracic petechiae are characteristic of the postmortem changes found in sudden infant death syndrome. The presence and distribution of these petechiae have been claimed as evidence for airway obstruction as the mechanism of death. In a group of young, mature rats that were free of infection, hypoxic asphyxia produced an insignificant number of petechiae, whereas in all littermates infected with an enzootic virus (Sendai) large numbers of petechiae with hypoxic asphyxia developed. Rats similarly infected, but killed with an overdose of pentobarbital sodium, had no petechiae. Most importantly, infected rats with unremitting airway obstruction were free of petechiae. Thus, the experimental conditions necessary for the presence of intrathoracic petechiae are profound hypoxia and infection, with persistent circulation and respiratory effort; persistent airway obstruction does not produce petechiae, with or without infection.

(Am J Dis Child **134:364-366, 1980)**

Sudden infant death syndrome (SIDS) is diagnosed in infants who die unexpectedly between the ages of 1 to 6 months and in whom inherently lethal pathology has been excluded. The disorder is the most frequent cause of death in that age group. There are some characteristic autopsy lesions, particularly intrathoracic petechiae and pulmonary edema. Handforth,[1] after producing petechiae in rats by airway obstruction, postulated that the petechiae were due to airway occlusion by laryngospasm. Beckwith[2,3] argued that the limited distribution of the intrathoracic petechiae establishes airway occlusion as the important factor.

We were surprised to find, after recreating Handforth's experiments,[4] that unremitting airway occlusion produced petechiae in only 7% of the rats, whereas death due to breathing 100% nitrogen produced petechiae in 80% to 87% (without and with anesthesia, respectively). These rats were all "retired breeder rats," 1 year of age or older. Subsequently, we attempted to identify the vascular source of the petechial hemorrhages, using our previously successful routine of hypoxic asphyxia. Unexpectedly, we could not produce petechiae by this method. Careful scrutiny showed that the only obvious difference between the earlier group of rats and the current ones that did not demonstrate petechiae, was in age: the new "resistant" rats were mature, but less than 3 months of age. The incidence and severity of enzootic infections increase with age in rats raised conventionally in large colonies; although some of the infections represent acute viral disease, chronic mycoplasma respiratory infection is progressive in its severity with increasing age.[5] Therefore, we decided to find out whether the presence of a respiratory infection was the crucial condition in the varying prevalence of petechiae. This relationship has major significance in the human cases of SIDS, since the majority of the infants are known to have mild upper respiratory infections (URIs),

with viral isolates obtained from 38% of the victims, and inflammation of the pharynx in more than 90%.[6]

MATERIALS AND METHODS

Twenty-four pathogen-free Sprague-Dawley rats (CD-CRL: DOBS CS [SD] BR), weighing 180 to 200 g, 45 to 60 days of age, 12 male and 12 female, were placed in cages isolated from other rats. Blood samples were obtained from each animal, and the antibody titers to Sendai virus were less than 1:10 by the hemagglutination inhibition test (HAI), which indicated no prior exposure to that virus. They were then separated into two groups of 12, with equal sex distribution. The experimental group A was inoculated with a stock virus, parainfluenza 1 (Sendai) ATCC VR 105. The inoculum was obtained by propagating stock virus in 10-day-old embryonating chick eggs, harvested after 48 hours, clarified by centrifugation, and stored at −70 °C. Median egg infectious dose for the virus was greater than 10^8, and the hemagglutination titer was 1,028. The virus was diluted 1:10 in sterile phosphate-buffered saline solution. Each experimental animal was lightly anesthetized with ether, and 0.05 mL of the Sendai dilution was instilled intranasally with a disposable microtiter pipette. The control rats, group B, were treated similarly, except that the diluted virus was inactivated.

Six days later, both groups of rats (12 with the live virus and 12 with the killed virus) were individually placed in 3-L jars that contained 100% nitrogen. Respiration usually ceased after one minute. Gasping commonly occurred one minute later, and all respiratory and cardiac activity had ceased by five minutes from the time of placement in the jar. The rat was removed from the jar, and the chest and abdomen were opened and the thoracic contents were removed en bloc. A direct, close-up photograph of the anterior aspect of the lungs was obtained immediately. Identifying data were placed on the back of the print. These photographs were then graded 0 to 4+ for the presence or absence of petechiae, without knowledge of the treatment group (Table). A score of 4+ was assigned for massive, bilateral, confluent petechiae; 1+ for one or two small petechiae in only one lung; 2+ for bilateral, but few and small petechiae; and 3+ for bilateral, numerous, but discrete lesions. We used a nonparametric test for comparison, the Wilcoxon two-sample test.

Ten additional rats similar in all respects to those in groups A and B were infected with the Sendai virus, and after six days were killed with pentobarbital sodium (40 mg) injected intraperitoneally (group C). These animals died of abrupt respiratory arrest, without gasping. A final group (D) of 12 rats identical in age, size, and sex as the other three groups were infected with the Sendai virus. After six days, they were anesthetized lightly with pentobarbital (3 mg/100 mg of body weight), the trachea was surgically exposed, and permanently occluded by cross-clamping.

Percentage of Rats With 2 to 4+ Petechiae

	Results, % (No.)		
	Present Study*		1973 Study†
Without respiratory infection, hypoxic asphyxia	Group B	0 (11)	. . .
With respiratory infection			
Hypoxic asphyxia	Group A	100 (12)	87 (15)
Pentobarbital sodium apnea	Group C	0 (10)	. . .

Cardiac arrest	. . .		27 (15)
Succinylcholine chloride apnea	. . .		20 (15)

*Data from this report on young, mature rats. Infection with acute, Sendai virus.
†Data from 1973 report.[4] Chronic mycoplasma infection assumed in these "retired breeder" rats.[5]

RESULTS

Three of the 12 control animals, group B, without infection and dead of hypoxia, had 1+ petechiae; nine had none. Of the 12 animals in group A exposed to live Sendai virus, one animal died prior to the hypoxic exposure; the other 11 all demonstrated bilateral petechiae when killed by hypoxia. Six had 2+ petechiae, three had 3+, and two had 4+ ($P < .01$).

One of the ten animals in group C, infected and killed by abrupt respiratory arrest with pentobarbital, had 1+ petechiae (no significant difference from the control group). In group D, infected and killed by airway obstruction one of 12 had 1+ petechiae (again, not significantly different from the control group). None of the rats from any of the four groups had petechiae on the ventral surfaces of the abdominal viscera.

COMMENT

We have combined the data from the four groups comprising this report with those of our earlier experiments in rats.[4] To summarize the factors demonstrated to produce petechiae, we have used the earlier method of presenting the results, grouping 0 to 1+ as negative and 2 to 4+ as positive. In young, uninfected animals, petechiae were rarely seen, even with hypoxic asphyxia, whereas the combination caused petechiae in all of the animals. On the other hand, infection was not sufficient to produce petechiae in the absence of respiratory effort (overdose of pentobarbital or succinylcholine chloride) nor with airway occlusion. Abrupt cardiac arrest, produced by administration of intracardiac potassium chloride, was earlier found to produce petechiae in only four of 15 rats (27%), which suggests that persistence of circulation during hypoxia facilitated the development of petechiae. Thus, common factors that are required to produce intrathoracic petechiae are infection and hypoxia, with respiratory movement and intact circulation.

Most striking is the failure of airway obstruction to produce petechiae, with or without infection. Handforth[1] and Beckwith[2] pointed out that the petechiae are intrathoracic in SIDS, and not on abdominal viscera. They deduced that negative pressure within the thorax was causally related, presumably by increasing the transmural pressure in the pulmonary blood vessels, causing rupture. However, the pulmonary vessels are completely within the thorax, and the drop in pressure with a deep inspiratory effort is directly transmitted to those vessels.

There are examples from forensic pathology that agree with our findings of no petechiae with airway occlusion. Marshall[7] reported that petechiae were infrequent in asphyxiation cases due to plastic bags or aspirated foreign bodies, and Camps[8] stated that abrupt death by hanging

caused no petechiae. Examining for airway obstruction by postmortem roentgenography, we found only two victims of SIDS without a clear airway, out of 78.[9] A group of autopsy cases of infants dying of other causes showed one of 22 without a definite airway.

Sendai virus is a common pathogen in rats, and produces an acute respiratory infection, rarely lethal, similar to a human URI. Considering that most human infants dying with SIDS have URIs, which are not lethal for the healthy human, the parallel between the Sendai virus and the human viruses seems reasonable. A nonlethal virus may cause petechiae when the infection coincides with a lethal stress. In our rat model, the lethal factor was hypoxia, (with vigorous respiratory movements and an intact circulation) and postmortem evidence from human cases favors the same factor, hypoxia, in SIDS.[10] Although Naeye's evidence suggests chronic hypoxia, the acute episode resulting in death appears to be apnea, usually sleep apnea. Beginning with Steinschneider's in-hospital observations,[11] many centers have now observed infants with recurrent episodes of apnea, who require resuscitation.[12] Some of these patients have subsequently died and had autopsy findings consistent with SIDS. The majority of the observed or recorded apneic episodes are not obstructive, but central, based on the absence of respiratory effort.

Although viral respiratory infections are not usually lethal, and certainly small petechiae are not, the very high prevalence of URIs in SIDS victims suggests that URIs contribute in some way. The URIs seem to increase the frequency of prolonged apnea.[11] One mechanism that has been suggested is that the URI interferes with the infant's sleep, and sleep deprivation increases the chance of failure to arouse from sleep apnea in kittens.[13]

If sleep apnea leads to SIDS, which is associated with intrathoracic petechiae, the absence of petechiae in our experiments with apnea produced by pentobarbital or succinylcholine may seem to be in conflict. However, sleep apnea is a primary apnea, such as the apnea of the dive reflex[14]; primary apnea is usually followed by either arousal or hypoxic apnea. In animal experiments, hypoxic apnea is followed by gasping,[15] whereas gasping is suppressed by pentobarbital or succinylcholine. When not suppressed by drugs, gasping is usually effective in autoresuscitation in rats and in the newborn human; gasping may remain effective for the first three or four weeks in human infants and could account for the sparing of the first month of life by SIDS. If recurrent episodes of apnea and gasping occurred, the pathologic changes found by Naeye[10] in victims of SIDS could be accounted for, including petechiae.

In conclusion, we find that the causes of the intrathoracic petechiae in rats are multifactorial: infection and hypoxia, with persistent respiration and circulation. Persistent airway obstruction does not produce petechiae, with or without infection.

This investigation was supported by US Public Health Service grant HD-10340.

Esophageal Perforations in Premature Infants and Comments on the Diagnosis

Thomas A. Clarke, MB, FRCP(C); Ronald W. Coen, MD; Bernard Feldman, MD, MPH; LuAnn Papile, MD

• **Traumatic perforation of the esophagus follows oropharyngeal suctioning or endotracheal intubation. The diagnosis frequently is made from a routine chest roentgenogram that shows a nasogastric tube in the right pleural space with or without a pneumothorax. The lesion is seen most often in infants of low birth weight.**

(*Am J Dis Child* 134:367-368, 1980)

In the reported cases[1-7] of complete perforation of the esophagus, the authors have noted the traumatic cause of the lesion and discussed the aspects of diagnosis and treatment.

See p 417.

None of the reports have emphasized that perforation of the right parietal pleura and a right pneumothorax are findings that frequently lead to the diagnosis of the esophageal lesion. This observation was made after our experiences with esophageal perforations in five premature infants. This event provides an important clue in the diagnosis.

From the Department of Pediatrics, University of California at San Diego, La Jolla, Calif (Drs Clarke and Coen), the Department of Pediatrics of Southwest Neonatal Center, Las Vegas, Nev (Dr Feldman), and the Department of Pediatrics, the University of New Mexico, Albuquerque (Dr Papile).

Reprint requests to Department of Pediatrics/H638a, University Hospital, 225 W Dickinson, San Diego, CA 92103.

SUBJECTS AND METHODS

Diagnosis of esophageal perforation was made in five of 1,700 infants who were admitted to three regional neonatal intensive care centers. The clinical features of these five cases are summarized in the Table. All the infants had a low birth weight and were premature by gestational age. Four of the five infants were ventilated mechanically when the diagnosis of perforation was made. In one of the five infants, the esophageal perforations were not identified until the time of autopsy, even though mediastinitis had been noted two days prior to death during surgical ligation of a patent ductus arteriosus. In that case, one perforation was seen in the posterior esophagus above the carina of the trachea and a second was seen in the esophagus below the carina. The medial portion of the right parietal pleura was intact.

In the four remaining cases, the diagnosis was made primarily by a chest roentgenogram. A right pneumothorax was present in all four cases. In infants 1, 3, and 5, a nasogastric tube was seen in the right pleural space at the time that the pneumothorax was identified on the chest roentgenogram. In infants 1, 2, and 3, a "milky drainage" followed feedings and was collected from the right pleural cavity via chest tube or thoracotomy hole.

All the infants were treated conservatively with medical management, including antibiotics. There were three deaths. Two resulted from causes that related to the presence of esophageal injury, namely sepsis and respiratory failure.

COMMENT

The salient features of 17 reported cases of traumatic perforation of the esophagus are as follows. Of the 17 infants studied, 14 weighed less than 2,500 g. The frequency with which esophageal perforations occur in low birth weight infants probably relates to the fact that these infants often have pulmonary disease and require intubation and oropharyngeal suctioning, or require frequent, intermittent gavage feedings by nasogastric tube.

In the majority of cases, the diagnosis was made with a chest roentgenogram during the first ten days after birth. In 11 of 17 cases, a nasogastric tube was seen to lie in the right pleural space, and in nine of these there was an accompanying right pneumothorax. Although Kassner et al[3] have noted the clinically "silent" nature of this lesion, in our experiences pneumothoraces and milky drainage from a chest tube are clinical signs that cause alarm.

The involvement of the right pleural space and complete perforations of the esophagus seem unique and may have an anatomical basis. As it descends in the posterior mediastinum, the esophagus contacts the right parietal pleura just below the bifurcation of the trachea,[9,10] and then swings to the left a few centimeters above the diaphragm to contact the left parietal pleura and brace against the descending aorta. It is our hypothesis that the rightward deviation of the esophagus and inadequate extramural support of its right side wall predisposes the

Esophageal Perforations

*At autopsy.

right parietal pleura to perforation by a stiff suction catheter or an endotracheal tube with a stylet. Unfortunately, the autopsy findings in infant 4 do not support this hypothesis. However, this is one case in which the right parietal pleura was not involved.

We also have some doubt about the spontaneity of so-called "spontaneous" esophageal perforations,[8] since a right pneumothorax was present in 11 of the 13 reported cases. The predilection for the right side in these cases leads us to speculate that suctioning at birth may have been an underlying trauma and possible cause.

We remind those who intubate and suction newborn infants, particularly infants with low birth weight, to exercise care in placing a stylet within an endotracheal tube and to note carefully the position of the head and neck during intubation. The airway is most patent when the neck is horizontal to the table.[11] Hyperextension of the neck may play a role in the genesis of esophageal tears, particularly when a stiffened catheter or endotracheal tube is introduced into the oropharynx. The frequency with which esophageal injury occurs may relate inversely to the experience of the person performing the intubation or suctioning.

In summary, esophageal perforations are rare, especially when one considers the number of infants who are suctioned and intubated without incident every day. When perforations occur, however, they frequently are heralded by roentgenographic findings of a nasogastric tube lying free in the right pleural space together with a right pneumothorax. These signs are important clues to the diagnosis of complete perforation of the esophagus.

Urinary Infection in Infants and Preschool Children

Five-Year Follow-up

Sharon R. Siegel, MD; Bernard Siegel, MD; Burton Z. Sokoloff, MD; Marvin H. Kanter, MD

• A group of 1,617 infants and 1,711 preschool children were studied for symptomatic and asymptomatic urinary infection and followed up for three to five years. Asymptomatic bacteriuria was found in 1.8% of female infants, 0.5% of male infants, 0.8% of preschool girls, and none of the preschool boys. Seventeen percent of the infants and 13% of the preschool children with urinary infection studied roentgenographically had upper tract damage; 46% of the infants and 9% of the preschool children had vesicoureteral reflux. Infants with normal urinary tracts and urinary infection with or without reflux tended to have recurrent infection, whereas the kidneys remained anatomically normal. The infants with high-risk lesions, such as obstructive uropathy and vesicoureteral junction ectopia and deformity, had substantial bacteriuria on screening culture.

(*Am J Dis Child* 134:369-372, 1980)

It is possible to recognize the asymptomatic infant and child with significant bacteriuria.[1] The purposes of this study were: (1) to define the prevalence of asymptomatic urinary infection in infants and preschool children; (2) to determine the frequency and type of urological abnormalities associated with asymptomatic and symptomatic urinary infection; and (3) to provide five-year follow-up of the infants and preschool children with urinary infection.

SUBJECTS AND METHODS

All children (a total of 1,617 infants and 1,711 preschool children; 1,715 girls and 1,613 boys) seen between January 1970 and January 1975 in a pediatric office that serves a middle- to upper-middle-class population were studied. All children with symptomatic urinary infection (group 1) and all normal children with no symptoms of urinary infection who were tested for bacteriuria (group 2) were included. The normal children were selected from those children brought to the office for a "well-child" checkup. No parent refused the urine culture procedure as part of the well-child evaluation. The normal children (group 2) were tested at 3 to 6 months, 15 to 18 months, 3 years, and 4 years of age. Groups 1 and 2 are categorized into four subgroups: group A, urinary infection without vesicoureteral reflux or anatomical abnormality; group B, urinary infection associated with vesicoureteral reflux but no anatomical abnormality; group C, urinary infection associated with a congenital obstructive uropathy; and group D, urinary infection associated with vesicoureteral junction ectopia.

CULTURE TECHNIQUE AND IMPLICATIONS

The child's perineal area was cleaned with benzalkonium antiseptic solution applied by a trained office assistant, and the urine specimen was collected with a sterile pediatric collector or urine container. The children who did not urinate within 30 to 45 minutes had cultures taken on a subsequent visit.

Within five minutes after collection, the urine was tested for bacteriuria using the miniature culture (Testuria Kit)[2,3]; was tested for levels of protein, blood, and glucose; and was centrifuged and examined for pyuria under high-power lens. If the culture was positive (> 25 colonies indicates > 100,000 colonies/mL on standard pour plate), a second voided specimen was obtained by the technique described earlier for quantitative bacterial count by standard pour plate technique. A third urine specimen was obtained by urethral catheterization after informed consent during the last three years of the screening program.

The well child with no symptoms of urinary infection was considered to have a urinary tract infection if a colony count of greater than 100,000/mL of the same organism was obtained on the two clean voided cultures during the first two years of the study. During the last three years of the study, the well child was regarded as having a urinary infection if two

clean voided cultures showing greater than 100,000 colonies/mL of the same organism plus substantial bacteriuria by urethral catheterization were obtained. The sick child with symptoms of urinary infection was considered infected if one or two urine cultures had greater than 100,000 colonies/mL.

Children with positive cultures as just defined were placed on a regimen for two to three weeks of sulfisoxazole acetyl, ampicillin sodium, or the antibiotic indicated on culture sensitivities. An intravenous pyelogram (IVP) and cystourethrogram made while voiding (VCU) were obtained after the treatment was completed.

The IVP was considered abnormal if there was (1) local parenchymal loss; (2) calyceal distortion and dilation;

and (3) dilation of the ureters. The following roentgenographic grading of the vesicoureteral reflux was used: grade 1, minimal reflux into lower ureter; grade 2, entire ureter filled; grade 3, upper urinary tract filled; grade 4, grade 3 plus severe distention of the renal pelvis and calyces.

Those children with abnormal roentgenographic findings, inability to clear the initial infection with one or more courses of therapy, or repeated infection had consultation and cystoscopy by a urologist. The children with recurrent infection were placed on a program consisting of nitrofurantoin (25 to 50 mg at night from six weeks to one year, depending on the size of the child and recurrent rate of infection) and increased fluid intake. These children were subsequently followed up with urinalysis, urine cultures, roentgenography, and surgery when indicated by the urologist in communication with the pediatrician. Those children with urinary infection and normal roentgenograms were subsequently followed up by the pediatrician.

RESULTS

Substantial asymptomatic bacteriuria occurred in 15/420 (3.6%) of the female infants (< 1 year 11 months old) and 7/391 (1.8%) of the male infants. It occurred in 7/375 (1.9%) of the preschool (< 4 years 11 months old) girls and 0/285 of the preschool boys. These figures are based on two clean catch urine cultures obtained during the first two years of the study. After the addition of urethral catheterization during the last three years of the study, asymptomatic bacteriuria occurred in 7/390 (1.8%) of the female infants and 2/416 (0.5%) of the male infants and also in 4/530 (0.8%) of the preschool girls and 0/521 of the preschool boys. However, this decrease was not statistically significant in any of the groups. Urinary infection was diagnosed in 42 children younger than 1 year of age, in 17 between 1 and 2 years, and in 44 between 2 and 5 years of age. The organisms present in the infants were *Escherichia coli* (55%), *Proteus* (22%), *Staphylococcus aureus* (11%), and *Pseudomonas* (11%). *Escherichia coli* was present in all of the preschool children.

Between January 1970 and January 1975, 25 female infants, three male infants, 28 preschool girls, and four preschool boys were recognized as having symptomatic urinary infection during visits to the office because of sickness. The prevalence of symptomatic urinary infection is unknown.

Table 1 gives the results of roentgenographic evaluation of the infants and children with asymptomatic and symptomatic urinary infection. Eight of the 47 infants whose conditions were studied by IVP had upper tract damage. Ten of the 43 infants with conditions studied by VCU had grades 1 to 2 vesicoureteral reflux, seven had grade 3, and three had grade 4. Six of the 31 preschool cases studied by IVP showed upper tract damage; one of the 27 studied by VCU was grade 1 to 2 vesicoureteral reflux, and one was grade 4.

There was 52 children (group A) who had urinary infection without vesicoureteral reflux or anatomical abnormalities. All initial IVPs and VCUs were normal. Recurrent infection occurred during the next three years.

Ten children (group B), all female, with normal urinary tracts had urinary infection associated with vesicoureteral reflux. Five had grade 3 and/or 4 reflux. Four of the nine followed up continued to have recurrent infection for the next three to five years. During the five-year follow-up of groups A and B, urine cultures were obtained at one- to two-month intervals for the first six months and then approximately at six-month intervals, after diagnosis of the urinary infection.

Table 2 gives the initial findings and five-year follow-up data for each child with congenital obstructive urinary tract abnormalities (group C) and Table 3 gives the findings for those with vesicoureteral junction

ectopia and deformity (group D). Ten (five infants and five preschool children) (group C) of the 78 (13%) who underwent roentgenographic studies had congenital obstructive urinary tract anomalies with reflux. Six (all infants) (group D) of the 78 (7.5%) whose conditions were studied roentgenographically had primary vesicoureteral reflux associated with vesicoureteral junction ectopia and/or deformity.

Twenty-four children, 22 female and two male, with symptomatic or asymptomatic bacteriuria had no initial IVP or VCU. The parents refused permission or the children were lost to follow-up. Of the 12 followed up one to three years, none had further infection.

COMMENT

The reduction in the number of urinary infections diagnosed by the addition of urethral catheterization to two clean catch cultures ("Results" section) was not statistically significant. However, the clean catch group was studied prior to the urethral catheterization group. Studies by Pryles et al[4] of 42 children and Redman and Bissada[5] of 200 infants showed no urinary infection secondary to a single urethral catheterization. No child in the study had a urinary infection after a single urethral catheterization. Urethral catheterization was found to be an easier, less traumatic, and more successful technique to diagnose cases of older infants and preschool children as outpatients than was suprapubic aspiration.

Vesicoureteral reflux (Table 1) was found in 46% of infants vs 9% of preschool children. Roberts and Riopelle[6] have shown in infant monkeys that vesicoureteral reflux disappears with maturity. The amount of anatomical upper tract damage (Table 1) was similar in the infants (17%) and preschool children (19%).

During the three- to five-year follow-up of group A, the 52 children who had urinary infection without associated reflux, all of whom had normal IVPs and VCUs initially, were anatomically normal. Their infections recurred primarily within the first year and stopped within three years.

In group B, of the ten children, all female, who had vesicoureteral reflux secondary to urinary infection, one child had an abnormal IVP but subsequent repeated IVP was normal. Recurrent infection was more common in group B than in group A and continued for more than three years without a change in the IVPs. Although the children with reflux had a greater number of recurrent infections for a longer period of time, urinary infection in a normal urinary tract with or without reflux had a good prognosis when there was early treatment of recurrent urinary infections.

In most instances, reflux with infection leading to pyelonephritis seems to be necessary for a kidney to have impaired growth.[7] Therefore, early diagnosis and treatment of urinary infection with follow-up should decrease the morbidity in infants and young children with rapidly growing kidneys.

Table 2 gives the follow-up of the two groups with high risk for development of chronic pyelonephritis. Group C contains ten infants and children with obstructive uropathy, eight of whom had abnormal initial IVPs. Group D contains the infants and children with vesicoureteral junction ectopia and/or deformity with grade 3 and/or 4 primary reflux and an abnormal initial IVP in 2/6. Three of ten in group C and 3/6 in group D were recognized as having asymptomatic bacteriuria when younger than 2 years of age (5/16 $<$ 12 months of age). The children with congenital obstructive uropathy (group C) who initially had symptomatic urinary infection had not been previously tested for asymptomatic bacteriuria in infancy. During the next three to five years, group C infants and children continued to have recurrent infection after surgical repair of the obstructive uropathy. However, the follow-up IVPs were abnormal in only two instead of eight. In group D, one infant had a ureterocystostomy, with no further infection. Others were treated conservatively, and all had normal IVPs three to five years later. Willscher et al[8] showed that surgery on children with primary reflux was successful in preventing recurrent postoperative infection, with a statistically significant ($P < .05$) increase in renal growth. Early diagnosis, surgical treatment, and prompt treatment of recurrent infection seemed to reduce the morbidity and mortality in these high-risk groups. An 11% mortality among infants with urinary infection has been reported.[9]

The fact that infants seen between 1970 and 1975 with obstructive uropathy and vesicoureteral junction ectopia and deformity had substantial bacteriuria suggests that such cultures can help in diagnosing these high-risk groups earlier and in possibly changing the natural history. The ten-year study of Randolph et al[10] suggests that further urinary infections can be prevented.

Ayerst Laboratories, New York, supplied the Testuria kits, and Sterilon Corp, Braintree, MA, supplied the sterile pediatric urine bags.

Richard Glassock, MD, provided criticism of the manuscript.

Hyaline Membrane Disease

A Controlled Study of Inspiratory to Expiratory Ratio in Its Management by Ventilator

Robert C. Spahr, MD; Alan M. Klein, MD; David R. Brown, MD; Hugh M. MacDonald, MD; Ian R. Holzman, MD

• Sixty-nine neonates with severe hyaline membrane disease (HMD) were mechanically ventilated using either a 1:2 or a 2:1 inspiratory to expiratory (I/E) ratio. Survivors in the 2:1 group required a lower fraction of oxygen in the inspired air (FiO_2) and lower end-expiratory pressure to achieve satisfactory oxygenation. During the first week of life, time of exposure to $FiO_2 > 0.60$ while being mechanically ventilated was 29.7 ± 7.5 hours for the 1:2 group and 6.9 ± 2.7 hours for the 2:1 group, while time of exposure to end-expiratory pressure > 3 cm H_2O was 49.4 ± 7.9 hours for the 1:2 group and 13.4 ± 7.4 hours for the 2:1 group. Mortality and the incidence of air leak, patent ductus arteriosus, intraventricular hemorrhage, necrotizing enterocolitis, bronchopulmonary dysplasia, and pulmonary hemorrhage were not different for the two groups. Using an increased I/E ratio during the acute phase of HMD improved oxygenation but did not alter morbidity or mortality.

***(Am J Dis Child* 134:373-376, 1980)**

Hyaline membrane disease (HMD) is a major cause of respiratory failure in the neonatal period. During the past decade, mechanical ventilation has become an accepted therapy for this disease. Increasing the inspiratory to expiratory (I/E) ratio is a technique that has been used to improve the oxygenation of mechanically ventilated babies.[1-6] A retrospective review[7] has suggested that increasing the I/E ratio increases the arterial partial pressure of oxygen (Pao_2) at lower peak inspiratory pressure, increases the survival rate, and reduces the incidence of bronchopulmonary dysplasia (BPD) for babies mechanically ventilated for HMD.

Although use of an increased I/E ratio has become an accepted method for improving oxygenation,[8,9] its efficacy has not been established in a prospective, controlled, clinical trial. To determine the usefulness of this technique, patients with severe HMD requiring mechanical ventilation were randomly and prospectively assigned to either a 1:2 or a 2:1 I/E ratio treatment group. We then examined the effect of this therapy on mortality, morbidity, the required fraction of oxygen in the inspired air (FiO_2), and respirator pressure settings.

PATIENTS AND METHODS

Patients

The study population consisted of all patients (n = 74), admitted to the Magee-Womens Hospital intensive care nursery in Pittsburgh during the 12-month period ending in December 1978, who required mechanical ventilation for the treatment of HMD. The diagnosis of HMD was based on the clinical findings of cyanosis, expiratory grunting, nasal flaring, intercostal retractions, and reticulogranular infiltrates on chest roentgenogram. Indications for mechanical ventilation in these patients with HMD were either (1) a $Pao_2 < 50$ mm Hg when the patient was exposed to continuous distending pressure of 8 cm H_2O and $FiO_2 > 0.80$ or (2) a pH < 7.25 that was unresponsive to other therapy or (3) apnea with frequently occurring bradycardia. Of the 74 patients admitted to the study, five were later excluded because they had a surgically induced pneumothorax at the time of patent ductus arteriosus (PDA) ligation (one in each group), evidence of air leak prior to mechanical ventilation (one in the 1:2 group), documented sepsis (one in the 1:2 group), or received tubocurarine chloride (one in the 2:1 group). Patients were prospectively matched for birth weight, sex, and place of birth (at Magee-Womens Hospital vs a referral hospital) and then randomly assigned by coin toss to either a 1:2 or 2:1 I/E ratio treatment group.

Methods

The patients were ventilated using time-cycled, pressure-limited respirators (Baby Bird respirators, Bird Corp, Palm Springs, Calif) that were initially set at an inspiratory pressure of 22 cm H_2O, an end-expiratory pressure of 3 cm H_2O, a flow rate of 10 L/min, a rate of 20 cycles per minute, and an FiO_2 sufficient to relieve cyanosis. We found that a square pressure wave was generated when the machine was adjusted in this manner. The I/E ratio and the flow rate remained constant throughout the course of mechanical ventilation as long as the ventilator rate was greater than 20 cycles per minute; at lower rates, the maximum inspiratory times were set at one and two s for the 1:2 and 2:1 groups, respectively.

The I/E ratios and inspiratory times were set using I/E ratio meters whose accuracy was checked with a stopwatch. Ventilator settings were checked for accuracy at least once an hour by inhalation therapists using an in-line pressure manometer. The settings and FiO_2 changes were adjusted to maintain the patient's Pao_2 at 45 to 60 mm Hg and the pH at 7.25 to 7.35. Alterations in inspired oxygen and/or end-expiratory pressure were made to prevent hypoxia while changes in rate (to a maximum of approximately 40 breaths per minute) and inspiratory pressure were made to prevent acidosis, hypercarbia, and hypoxia, when necessary. No attempts were made to inhibit spontaneous respirations. Patients were weaned from the ventilator using the method of Gregory.[10]

Except for ventilator management, study patients were treated according to the routines of the intensive care nursery. Babies received care in humidified, servo-controlled incubators, with heat shields for patients weighing < 1,200 g. Starting on

From the Division of Neonatology, Department of Pediatrics, University of Pittsburgh School of Medicine, Magee-Womens Hospital, Pittsburgh.

Reprint requests to Department of Pediatrics, Magee-Womens Hospital, Forbes Ave and Halket St, Pittsburgh, PA 15213 (Dr Holzman).

the fifth day of life, babies received daily supplemental multivitamins and vitamin E (15 IU) by gavage. Fluid was administered at a rate of 65 mL/kg/day initially and subsequently adjusted depending on changes in body weight.

Data obtained for each patient included laboratory determinations of pH and blood gases as well as recordings of ventilator settings. Arterial blood was sampled from umbilical, radial, or posterior tibial artery catheters at intervals determined by the clinical staff. A pH-blood gas analyzer was used to measure the pH and the blood gases. A daily tabulation was made of all measurements of the arterial partial pressure of carbon dioxide ($PaCo_2$), the Pao_2 measurements at 6 hours of age, 24 hours of age, and every 24 hours thereafter. Hourly values of measured FiO_2, ventilator rate, and respirator pressure gauge values for inspiratory pressure and end-expiratory pressure were also recorded.

Specific forms of morbidity that were tabulated included air leak, BPD, clinically important PDA, pulmonary hemorrhage, necrotizing enterocolitis, and intraventricular hemorrhage (IVH). Air leak was defined by roentgenographic evidence of pulmonary interstitial emphysema, pneumothorax, pneumomediastinum, pneumopericardium, pneumoperitoneum without evidence of bowel perforation, or massive air embolism. A PDA was diagnosed in any patient who had the classical murmur, collapsing pulses, and a hyperdynamic precordium[11]; a PDA was considered to be clinically important when the patient was symptomatic to the degree that therapy with furosemide and/or digoxin was started. Bronchopulmonary dysplasia was defined by the persistence of signs of respiratory distress in association with the typical roentgenographic findings[12] for patients who continued to require supplemental oxygen after 1 month of age. A diagnosis of IVH was made on the basis of the clinical syndrome,[13] computerized axial tomographic (CT) findings, or postmortem examination results.

Statistical analyses were performed using the χ^2 test or two-tailed Student's t test for unpaired data; a $P < .05$ was used to define statistical significance. The protocol for this study was approved by the Research Review and Human Experimentation Committee of Magee-Womens Hospital.

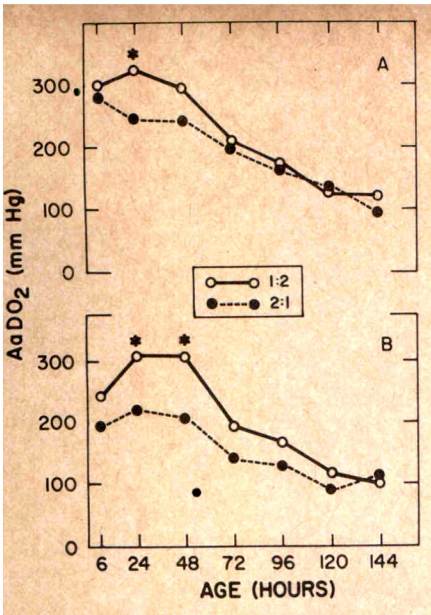
RESULTS

Amongst the 69 patients who met all the study criteria, 33 were assigned to the 1:2 I/E ratio group and 36 to the 2:1 group. There were no statistically significant differences between the groups in birth factors, indications for mechanical ventilation, age at the start of mechanical ventilation, or alveolar to arterial oxygen gradient ($AaDO_2$) at 6 hours of age (Table 1). This was true when comparing survivors (patients living longer than 28 days) or all patients in each group (Table 1). We analyzed ventilator data of survivors separately to eliminate patients with extensive CNS injury secondary to IVH whose duration of mechanical ventilation was unrelated to pulmonary disease.

Survivors ventilated with the 2:1 I/E ratio required lower FiO_2 and lower end-expiratory pressure to achieve satisfactory oxygenation (Ta-



Alveolar to arterial oxygen gradient ($AaDO_2$) for (A) all patients in each group and (B) survivors in each group. Asterisk indicates statistical significance ($P < .05$): the $AaDO_2$ = ([barometric pressure —partial pressure of water vapor in saturated air] $FiO_2 - Paco_2$) $- Pao_2$.[14] FiO_2 indicates fraction of oxygen in the inspired air.

Table 3.—Peak Ventilator Settings During Entire Course of Mechanical Ventilation*

	All Patients		Survivors	
	1:2 Group (n = 33)	2:1 Group (n = 36)	1:2 Group (n = 21)	2:1 Group (n = 18)
Peak inspiratory pressure, cm H_2O	29.7 ± 1.5	28.6 ± 1.6	26.0 ± 1.1	23.5 ± 0.9
Peak expiratory pressure, cm H_2O	4.7 ± 0.9	4.5 ± 0.3	4.6 ± 0.4	3.7 ± 0.4
Peak rate, cycles/min	30.4 ± 1.5	30.0 ± 1.5	26.2 ± 1.5	25.0 ± 2.0
Peak FiO_2	0.78 ± 0.04	0.81 ± 0.04	0.72 ± 0.05	0.68 ± 0.06

*Mean ± SEM. FiO_2 indicates fraction of oxygen in the inspired air.

ble 2). These results are based on analysis of data collected during the first week of life. The duration of exposure to $FiO_2 > 0.60$ while being mechanically ventilated was significantly less for the 2:1 group during the first week (6.9 ± 2.7 hours [mean ± SEM] vs 29.7 ± 7.5 hours, $P < .01$). During this period, survivors in the 2:1 group were also exposed to fewer hours of end-expiratory pressure greater than 3 cm H_2O (13.4 ± 7.4 hours vs 49.4 ± 7.9 hours, $P < .01$). The Figure presents data showing that the $AaDO_2$ was less in the 2:1 group when either all the patients (part A) or only the survivors (part B) were examined. The $AaDO_2$ for survivors in the 2:1 group was significantly lower at both 24 hours (223 ± 33 mm Hg vs 312 ± 30 mm Hg, $P < .05$) and 48 hours of age (213 ± 31 mm Hg vs 313 ± 30 mm Hg, $P < .05$) (Figure). The $AaDO_2$ values on the other days of the first week of life were not significantly different between the groups. The Pao_2 measurements used to calculate $AaDO_2$ were those obtained at 6 hours of age, then at 24-hour intervals after birth.

We did not find significant differences in other factors related to mechanical ventilation for survivors in the two groups. Carbon dioxide excretion was not significantly affected by the I/E ratio. The average daily $Paco_2$ during the first week of life (the mean of the mean of all $Paco_2$ measurements for each day) ranged from 41.9 ± 1.3 mm Hg to 47.3 ± 1.8 mm Hg for the 1:2 group and 37.5 ± 2.5 mm Hg to 47.5 ± 1.8 mm Hg for the 2:1 group; there were no group differences in $Paco_2$ on any of the first seven days. Two ventilator settings that alter the $Paco_2$, inspiratory pressure and rate, were not significantly different for the two groups (Table 2). Total hours of mechanical ventilation, intubation, and exposure to supplemental oxygen during the first week of life were not different for survivors in the groups (Table 2). Although duration of exposure to higher FiO_2 and end-expiratory pressure was different between the groups, there were no group differences in the highest peak inspiratory pressure, highest end-expiratory pressure, highest ventilator rate, or highest FiO_2 used (Table 3).

Overall morbidity was not significantly different between the groups (Table 4), nor were there differences in the occurrence of the specific forms of morbidity. Four patients in each group had pulmonary interstitial emphysema; six patients in the 1:2 group and ten in the 2:1 group each had a pneumothorax; one patient in each group had a pneumopericardium; one patient in each group had a pneumoperitoneum; and one patient in the 2:1 group had a massive air embolism. Many of these patients experienced more than one of these forms of air leak. All surviving patients with clinically significant PDA were successfully managed with medical therapy. Two survivors had IVH diagnosed by CT. Surviving patients had their maximal requirement for ventilator support during the first week of life. There were 11 survivors (seven in the 1:2 group and four in the 2:1 group) who continued to require mechanical ventilation after seven days of age. All of these patients had either air leak, PDA, pulmonary hemorrhage, or BPD. Peak inspiratory pressure used for these patients after the first week of life was 19.1 ± 1.2 cm H_2O and peak FiO_2 was 0.48 ± 0.08. Only one survivor, who was being treated for a pulmonary hemorrhage, required higher ventilator pressures in the second week than he did during the first week of life.

There were also no significant dif-

ferences in mortality between the groups. Twelve of the patients (36.4%) in the 1:2 group and 18 (50.0%) in the 2:1 group died in the first 28 days ($P > .20$). Although the proportion of infants less than 1,500 g was equal in both groups, the numerically greater mortality in the 2:1 group does occur in these low-birth-weight infants. The primary causes of death were IVH (11 cases in the 1:2 group and 15 in the 2:1 group) and air leak (one and three cases, respectively). One of the three cases in the 2:1 group whose death was clinically attributed to air leak also had an IVH diagnosed at autopsy. The diagnosis of IVH was made on clinical grounds in eight cases and at autopsy in 19. There were two deaths among "survivors" after 1 month of age, one in each group; one of these babies died at 5 months of BPD, and the other died at 6 months of nephrosis and BPD.

COMMENT

The results of our prospective study indicate that increasing the I/E ratio for babies with HMD who are mechanically ventilated improves oxygenation. Patients in the 2:1 group were adequately oxygenated at a lower FiO_2 and end-expiratory pressure during the first week of life. The improvement in oxygenation was most notable early in the course as shown by the significantly lower $AaDO_2$ for the 2:1 group at 24 and 48 hours of age. Inspiratory pressure, ventilator rate, and $Paco_2$ were not significantly different between the groups, suggesting that minute ventilation was not significantly influenced by the I/E ratios that we used.

An early study of I/E ratio[1] noted a significant decrease in right-to-left shunting, an increase in Pao_2, and no change in $Paco_2$ when the I/E ratio was increased from 1:2 to 4:1. This work was confirmed by a later study[2] that also suggested that continuous distending pressure acts synergistically with an increase in the I/E ratio to improve oxygenation. It has been suggested[2-6] that increasing the I/E ratio improves oxygenation through its effect on mean airway pressure. Although the exact mechanism is yet to be completely determined, the favorable action of increased I/E ratios on right-to-left shunting seems well established when using ventilators that generate square pressure waves.[4-6]

Despite the improvement in oxygenation associated with the increased I/E ratio during the first week of life, we did not find differences in morbidity between the groups. From their retrospective review, Reynolds and Taghizadeh[7] concluded that increasing the I/E ratio reduced morbidity by decreasing the incidence of BPD. We did not find a decreased incidence of BPD in our high I/E ratio group. This discrepancy in results may be due to the fact that we prospectively controlled for the use of end-expiratory pressure and the indications for mechanical ventilation while at the time of Reynolds and Taghizadeh's study[7] it was not possible to control for these variables. Concern has also been expressed[7] that the increase in mean airway pressure associated with the increased I/E ratio could have detrimental effects, especially if the high ratio were to be used after the acute phase of HMD when lung compliance improves. It has been suggested that the increased mean airway pressure could lead to air trapping and air leak or could compromise venous return and increase the risk of IVH. We did not find this to be the case. Our patients continued with their assigned I/E ratios throughout the course of mechanical ventilation, and those in the 2:1 group did not have a greater incidence of air leak or IVH.

We did not find that increasing the I/E ratio was associated with decreased mortality as reported by Reynolds and Taghizadeh.[7] The 50% mortality in our 2:1 group compares favorably with the 51% mortality in their increased I/E ratio group.[7] The difference in the studies lies in the 36% mortality of our 1:2 group and the 89% rate found by Reynolds and Taghizadeh[7] in their lower I/E ratio group. This difference could account for their ability to show a mortality effect of I/E ratio therapy whereas we could not. The discrepancy in mortality results of the two studies may reflect different criteria for beginning mechanical ventilation.

In conclusion, we found that the use of an increased I/E ratio is associated with improved oxygenation for babies receiving mechanical ventilation during the acute phase of HMD. We did not find any relationship of I/E ratio therapy to morbidity or mortality although the suggestion of a greater number of deaths in the 2:1 group deserves a note of caution. Our results also suggest that continuing the use of an increased I/E ratio after the acute phase of HMD does not increase morbidity; however, its use after this period probably offers little benefit since the improvement in oxygenation associated with the increased I/E ratio is most notable during the first several days of life.

The inhalation therapists and nurses of the Infant Referral Center of Magee-Womens Hospital, Pittsburgh, supported this project. Carleen Whelan and Margaret Guzik provided secretarial assistance in the preparation of the manuscript.

Macrocytosis and Pure RBC Anemia Caused by Azathioprine

Yves A. DeClerck, MD; Robert B. Ettenger, MD; Jorge A. Ortega, MD; Alfred J. Pennisi, MD

• Red blood cell macrocytosis is a well-known complication of azathioprine therapy. In a group of 91 patients receiving azathioprine immunosuppressive therapy for renal graft, the mean corpuscular volume determined by an electronic cell counter was substantially higher than in the normal population. Selective erythroid hypoplasia is another known but much less frequent complication of azathioprine use. The case of a child who had a selective erythroid hypoplasia while receiving azathioprine immunosuppressive therapy for renal graft is reported. The patient recovered as the drug therapy was discontinued. With progressive reintroduction of the drug, a second decrease in the hemoglobin was seen when a dose of 2 mg/kg was reached although with a smaller dose, no recurrence of anemia was observed.

(*Am J Dis Child* 134:377-379, 1980)

Azathioprine, an immunosuppressive drug with various uses in pediatrics, has a well-known toxic effect on hematopoietic cells. Megaloblastic erythropoiesis, leukopenia, and toxic panmyelopathy have previously been described.[1-4] Selective erythroid hypoplasia is an extremely rare side effect that has recently been described in adult patients.[5,6]

In our population of renal allograft recipients treated with azathioprine, we have noted two consequences of the drug affecting erythropoiesis. The first, RBC macrocytosis, was a common finding. The second, selective erythroid hypoplasia, was found in one case we describe.

RBC MACROCYTOSIS: PATIENTS AND METHODS

We selected 91 patients with transplants who had normal renal function and no exogenous anemia. Twelve patients were between 6 and 11 years old, 33 were between 12 and 17 years, and 46 were between 18 and 30 years. All patients were receiving azathioprine for a period of at least four months. Red blood cell mean corpuscular volume (MCV) was determined in each patient by an electronic cell counter, each patient having from one to four determinations in a period of three months.

Mean MCVs are given in the Table. Values were compared with normal values published by Dallman,[7,8] which were obtained using the same electronic cell counter model as the one used in this study. In the age groups 12 to 17 years and older than 18 years, the mean MCV was significantly higher than in the normal population ($P < .001$). Of the patients in these two groups, 39 had MCVs greater than 2 SDs from the mean. In the 6-to-11-years-of-age group, the difference was still significant ($P < .02$) although the number of patients was small. Only three patients in this group had MCVs greater than 2 SDs from the mean. Doses of azathioprine ranged between 0.8 mg/kg and 2.9 mg/kg, with a geometric mean of 1.95 mg/kg. Linear regression analysis showed that there was no relation between the RBC MCV and the dose of azathioprine (mg/kg). (MCV = 0.265 × dose + 95.01, $r = -.0192$).

SELECTIVE ERYTHROID HYPOPLASIA: REPORT OF A CASE

A 15-year-old boy had infantile polycystic kidney disease and congenital hepatic fibrosis diagnosed at the age of 6 months. In October 1974, he had end-stage renal disease and required maintenance hemodialysis. Because of portal hypertension, a splenorenal shunt with left nephrectomy and splenectomy were performed in December 1974. Four months later, he successfully received a cadaveric kidney transplant. Daily immunosuppressive therapy consisted of azathioprine, 100 mg (2.5 mg/kg), and prednisone in tapering dosage.

In May 1975, the patient had *Listeria monocytogenes meningitis* that was complicated by seizure activity requiring administration of phenobarbital sodium (2 mg/kg/day). In May 1977, the laboratory tests showed the following values: hemoglobin, 13.5 g/dL; hematocrit, 39.2%; and MCV, 112 fL. One month later, the hemoglobin level had decreased to 9.7 g/dL and two months later, it was 6.5 g/dL.

On Aug 23, 1977, he was admitted to Childrens Hospital of Los Angeles for investigation of anemia. Physical examination showed a short, prepubertal male adolescent with mild features of Cushing's syndrome and severe pallor. His liver was palpable 5 cm below the right costal margin. On admission, the patient was receiving 100 mg of azathioprine daily; 20 mg of prednisone daily; 40 mg (1 mg/kg) of phe-

Values for 91 Patients Receiving Azathioprine*

Age, yr	n	Hemoglobin, g/dL†	MCV, fL†	Normal MCV Mean, fL (−2 SD)‡	P
6-11	12	12.75 ± 1.63	93.14 ± 8.21	86 (76)	<.02
12-17	33	13.05 ± 1.77	93.94 ± 5.25	88 (78)	<.001
≥ 18	46	13.70 ± 1.85	96.58 ± 5.75	90 (80)	<.001

*MCV indicates mean corpuscular volume; fL, femtoliter.
†Mean value ±1 SD.
‡From Dallman.[7]

nobarbital sodium twice daily; and 250 mg of oral penicillin V potassium thrice daily. The hemoglobin level was 6.5 g/dL; hematocrit, 19.5%; MCV, 108 fL; mean corpuscular hemoglobin, 36.6 pg; mean corpuscular hemoglobin concentration, 32.9 g/dL; and reticulocyte count, 0.3%. The WBC count was 4,300/cu mm, with a normal differential cell count and a platelet count of 695,000/cu mm. Inspection of the smear showed anisocytosis and ovalocytosis of the RBCs with many Howell-Jolly bodies; no hypersegmented granulocytes were seen. Iron studies indicated an increased serum iron level of 255 μg/dL, with a transferrin saturation of 96%. Serum folate value was 4.2 ng/mL (normal > 2.3) and serum B_{12} level was 517 pg/dL (normal, 330 to 1,025). Coombs' test was negative. No occult blood was present in the stools.

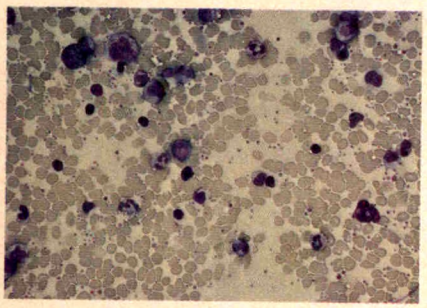

Fig 1.—Patient's bone marrow showing absence of erythroid precursors (Wright's stain, original magnification ×800).

Serum erythropoietin determined by the exhypoxic polycythemic mouse assay showed an activity of 24% uptake of ^{59}Fe. On this assay, normal nonanemic human serum has an erythropoietin activity of 1% or less.[9] Bone marrow examination showed a severe erythroid hypoplasia with a myeloid erythroid ratio of 12:1 (Fig 1). No megaloblastic changes were seen. Megakaryocytes were present in adequate numbers. Serum liver enzyme levels were normal, as were the partial thromboplastin time and the prothrombin time. Total bilirubin value was 0.3 mg/dL. No clinical evidence of graft rejection was detected, and the creatinine level remained in the 0.85 to 1.2 mg/dL range.

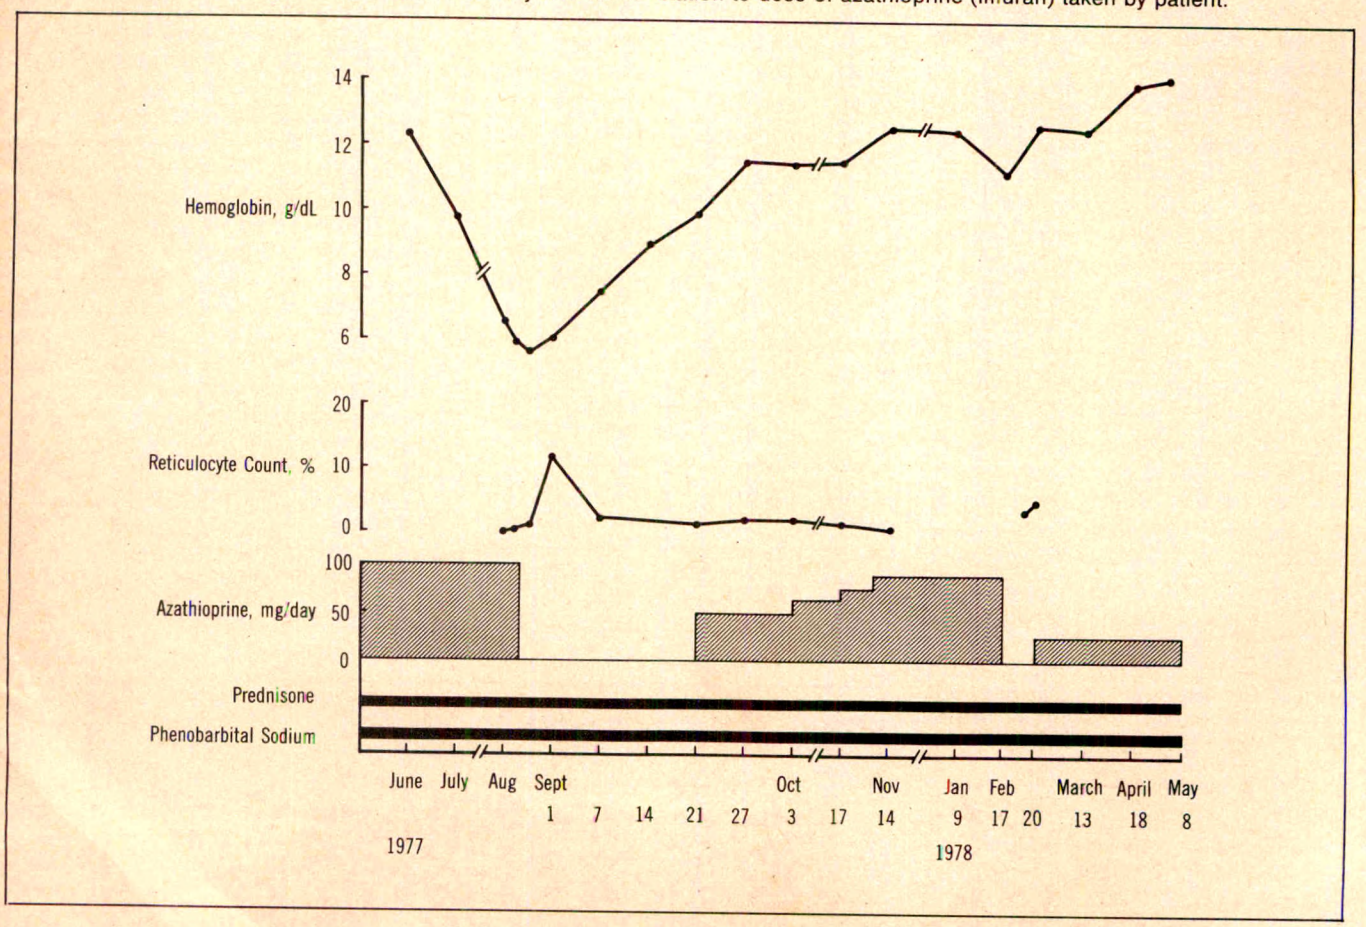
Because azathioprine toxicity was suspected, therapy with that drug was discontinued while treatment with all other medications was continued. No transfusion was given.

Six days after azathioprine therapy was discontinued, the reticulocyte count was 11.1%. Three weeks later, the hemoglobin value was 9 g/dL (Fig 2). Two months later, the hemoglobin value was 11.3 g/dL; hematocrit, 37%; and MCV, 105 fL. The azathioprine was reintroduced at a dose of 1.2 mg/kg/day and progressively increased to 2 mg/kg/day. However, in February 1978, the hemoglobin level began to decrease, and the drug therapy was again discontinued and was then restarted at 0.6 mg/kg/day. Presently, the hemoglobin value is 13.9 g/dL; hematocrit, 42.1%; and MCV, 88 fL. His serum creatinine level is 1.1 mg/dL.

COMMENT

In 1969, Kölle[3] described three types of bone marrow toxic effects induced by azathioprine: megaloblastic changes, defective granulocytopoiesis, and toxic panmyelopathy. In 1975, McGrath et al[5] reported macrocytic changes in 70 renal allograft recipients receiving azathioprine. The severity of the macrocytosis was found to be dose related. In our patients, macrocytosis was also a common finding although no dose relation between MCV and azathioprine was found. In the study of McGrath, the mean geometric dose of azathioprine was 2.83

Fig 2.—Hemoglobin value and reticulocyte count in relation to dose of azathioprine (Imuran) taken by patient.



mg/kg, which is higher than in our group (1.95 mg/kg) and could explain why no dose relation was found in our study. These authors also described two patients who had severe, pure erythroid hypoplasia six and two years after azathioprine therapy was started. In both patients, anemia was corrected by discontinuing therapy with the drug, and as in our patient, azathioprine therapy was reinstituted later at a lower dose, with maintenance of a normal hemoglobin value. More recently, Old et al[6] described two other patients who had a pure RBC anemia develop while receiving azathioprine.

Macrocytosis of RBCs and pure erythroid hypoplasia led us to suspect azathioprine toxicity as the cause of our patient's anemia. The dramatic increase in reticulocyte count and hemoglobin value observed after discontinuation of azathioprine therapy confirmed the suspected diagnosis. Normal serum folate and B_{12} levels excluded deficiency of these vitamins as cause of his anemia. Megaloblastic anemia, but not erythroid hypoplasia, has been described in association with chronic administration of anticonvulsant drugs such as phenobarbital and phenytoin (diphenylhydantoin). In these cases, a low serum folate level was found, and the anemia responded to the oral administration of folate without discontinuation of therapy with the anticonvulsant drugs.[10] Macrocytosis is also seen in chronic liver disease. It is thought to be due to folate deficiency, hemolysis, or acute blood loss,[11] the last two associated with an accelerated maturation and liberation of macrocytic reticulocytes. None of these factors were present in our patient.

Acquired acute pure RBC aplasia is a relatively uncommon disorder in childhood, mainly reported in patients with chronic hemolytic diseases.[12,13] The term "aplastic crisis" is frequently used to describe this transient aplasia associated with a rapid decrease in hemoglobin concentration in patients who already have a decreased RBC survival. There was no evidence of chronic hemolytic disease in our patient. Another cause of acute RBC asplasia is infection.[12-14] Although serologic tests were not performed in our patient to eliminate these possibilities, clinical findings and course did not suggest infection. Autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis; acute renal failure; severe nutritional deficiency; and neoplasm, such as leukemia, lymphoma, and multiple myeloma have also been described with pure RBC aplasia.[15] However, no evidence of any of these diseases have been observed during the period the patient has been followed up. Finally, transient erythroblastopenia of childhood has been described by Wranne,[16] in four children aged 8 months to 4 years. Although this possibility cannot be excluded on clinical grounds, the patient's age and the rapid increase in hemoglobin after discontinuation of azathioprine are more consistent with drug-induced erythroblastopenia.

A high erythropoietin activity has been described[17] in association with renal graft rejection. However, no evidence of rejection was observed in our patient. We interpret the high erythropoietin activity as a normal physiologic response to the anemia. The high serum iron level and transferrin saturation are explained by the selective erythroblastopenia and lack of iron utilization.

Azathioprine, a derivative of mercaptopurine, is a thiopurine. It interferes with de novo purine synthesis, and it inhibits DNA and RNA synthesis. Multiple sites of action have been demonstrated for these thiopurines and their derivatives,[18] including inhibition of purine incorporation into RNA and DNA. Megaloblastosis is thought to be the result of an imbalance between DNA and RNA synthesis, with impairment of the DNA without equivalent impairment of RNA and protein synthesis. According to this hypothesis, azathioprine inhibits DNA synthesis more than RNA synthesis, resulting in megaloblastosis.

The mechanism of selective erythroid hypoplasia is poorly understood. The high erythropoietin activity observed suggests that azathioprine does not inhibit the synthesis of erythropoietin. Since many patients receiving azathioprine have macrocytosis but only a few have selective erythroid hypoplasia, it may be speculated that an additional factor such as infection or a toxin may precipitate the anemia.

Macrocytosis is a common observation in patients taking azathioprine and does not necessitate discontinuation of therapy with the drug. Selective erythroid hypoplasia may seldom be seen and should be suspected in case of rapid development of anemia. Discontinuation of use of the drug is associated with recovery from anemia, and recurrence of anemia is not seen if treatment with the drug is restarted later at a lower dose.

Have you ruled out cow-milk sensitivity?

The physical symptoms are many and varied: diarrhea, colic, eczema, asthma, vomiting, bronchitis, rhinitis. They can be coupled with behavioral symptoms: repeated refusal of the nursing bottle . . . general fussiness.[1-3]

Alone or together, the manifestations of milk sensitivity are an unnecessary burden for the infant . . . and parents. More important, if unchecked the allergic syndromes can lead to failure to thrive and other serious health problems.[4]

With Isomil® Soy Protein Formula you can avoid the symptoms of milk sensitivity and help confirm your initial diagnosis.

Moreover, Isomil promotes normal growth.[2,5] It looks like milk, it pours like milk and has a pleasant aroma, which help insure acceptability. Unlike milk, Isomil is lactose free. It avoids the possibility of prolonged or recurring diarrhea caused by lactose intolerance.

Consider the possibility of milk sensitivity when associated symptoms are presented. "A high index of suspicion" is essential to its prompt detection.[2,6]

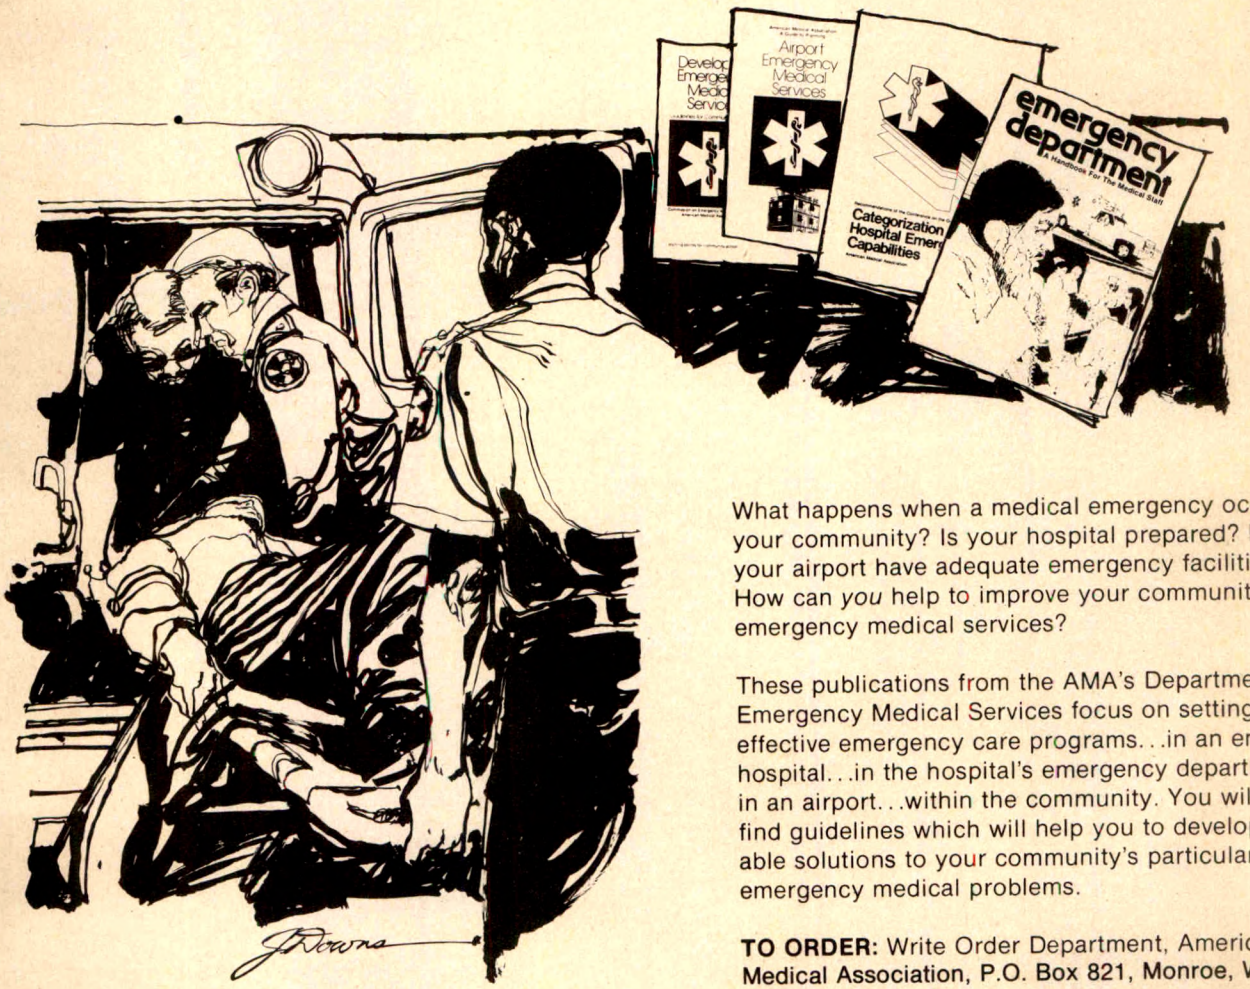
How Can You Help to Improve Your Community's Emergency Preparedness?

Consult these AMA Emergency Medical Care publications.



What happens when a medical emergency occurs in your community? Is your hospital prepared? Does your airport have adequate emergency facilities? How can *you* help to improve your community's emergency medical services?

These publications from the AMA's Department of Emergency Medical Services focus on setting up effective emergency care programs...in an entire hospital...in the hospital's emergency department... in an airport...within the community. You will find guidelines which will help you to develop workable solutions to your community's particular emergency medical problems.

TO ORDER: Write Order Department, American Medical Association, P.O. Box 821, Monroe, WI 53566. Please specify title, OP number, and include payment with your order. Allow 4-5 weeks for delivery.

PUBLICATIONS

Categorization of Hospital Emergency Capabilities (OP-387) $.55
The Commission on Emergency Medical Services of the AMA sets forth recommended guidelines for four categories of hospital emergency services for adults, children and infants, including newborns, that could function in community systems of emergency medical capabilities.

Emergency Department--Handbook for Medical Staff (OP-131 $2.00
How can the emergency department be an effective area for medical education? What are its legal implications? These and other related topics are explored in this manual which helps to establish workable solutions to problems in the emergency department.

Developing Emergency Medical Services--Guidelines for Community Councils (OP-386) $.75
In an effort to upgrade emergency medical care and reduce the number of needless accidental deaths, the AMA's Commission on Emergency Medical Services provides guidelines which deal with the establishment of community councils on emergency medical services and the various stages of developing good emergency medical services.

Airport Emergency Medical Services
(OP-085) $.85
This new guide outlines the major functions of an emergency medical services plan, plus the key elements in providing such services, which should be common to all airports. Includes illustrations and appendices.

NOW PETER

Attention Deficit Disorders* under control...
His natural abilities are coming through

Now Peter's enjoying more things at play as well as in school. He works better with his teacher and classmates... likes doing things with his dad... gets more natural pleasure out of family and friends.

Now that his concentration is improved, his natural abilities are coming through. He's functioning better. Under a well-integrated program of treatment for Attention Deficit Disorders (ADD), hyperactivity and impulsiveness are markedly reduced.

Ritalin (methylphenidate) can be a vital part of his regimen. With adjunctive use of Ritalin, many ADD children are better able to control hyperkinetic behavior —act in a more natural and appropriate manner.

A 20-year record of proven efficacy

Over the years, Ritalin has become an established choice for pharmacotherapy of ADD. In a report by the

BEHAVES MORE NATURALLY.

National Council on Child Health,[1] Ritalin was described as among the most effective and best-documented agents for stimulant therapy in hyperkinetic children.

Reduces hyperactivity, impulsive behavior

Ritalin has a well-documented record of success in relieving the dominant symptoms of ADD. As it reduces distractibility, disorganized behavior and hyperactivity, improved school performance usually results,[2,3] as well as better peer interaction.[2]

Generally well tolerated

Although side effects may occur with Ritalin, they are generally not serious. During prolonged therapy, anorexia, weight loss, and insomnia are among the most frequently encountered adverse reactions. (See Adverse Reactions section of the prescribing information.) Even though most children require long-term treatment, there is little evidence of habituation.[1]

Therapy with Ritalin should be considered only after a medical diagnosis of ADD has been confirmed. Dosage can usually be interrupted during weekends and vacations. In some cases, these drug holidays reveal "stabilization" in the child's behavior without medication. They may permit a reduction in dosage and eventual discontinuation of drug therapy if warranted.

*Attention Deficit Disorders: new designation by the American Psychiatric Association; formerly called Minimal Brain Dysfunction (MBD) or Hyperkinetic Syndrome.

TABLETS

INDICATIONS

Attention Deficit Disorders (previously known as Minimal Brain Dysfunction in Children). Other terms being used to describe the behavioral syndrome below include: Hyperkinetic Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, Minor Cerebral Dysfunction.

Ritalin is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate-to-severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Special Diagnostic Considerations

Specific etiology of this syndrome is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate-to-severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with this syndrome. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin. Clinical experience suggests that in psychotic children, administration of Ritalin may exacerbate symptoms of behavior disturbance and thought disorder.

Ritalin should not be used for the prevention or treatment of normal fatigue states.

There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.

Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

Drug treatment is not indicated in all cases of this behavioral syndrome and should be considered only in light of the complete history and evaluation of the child. The decision to prescribe Ritalin should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with Ritalin is usually not indicated.

Long-term effects of Ritalin in children have not been well established.

The Ritalin tablets (5 and 20 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

Dispense in tight, light-resistant container (USP).

Occult Anterior Sacral Meningocele

Thomas E. Sumner, MD; James E. Crowe, MD; Charles R. Phelps II, MD; Roger W. Park, MD

• Anterior sacral meningocele is a rare congenital malformation consisting of a spinal fluid-filled sac in the pelvis communicating by a small neck with the spinal subarachnoid space through a sacral defect. This entity should be considered if the characteristic scimitar sacrum is observed on a pelvic roentgenogram. If signs and symptoms also suggest a meningocele, special studies such as ultrasonography and myelography are indicated to establish the diagnosis of an anterior sacral meningocele. Computerized tomography provides additional evidence of spinal-abdominal extension of this lesion.

(*Am J Dis Child* 134:385-386, 1980)

An anterior sacral meningocele arises from a partial or total defect of the sacrum and coccyx, through which meninges herniate like a cyst. Though rare, it is occult and deaths may occur from meningitis, spontaneous rupture, and obstructed labor. This report describes a young girl with severe constipation and fecal incontinence caused by an anterior sacral meningocele. Sacral roentgenograms invariably disclose some abnormality in this entity.

REPORT OF A CASE

A 7-year-old girl was referred for evaluation of fecal incontinence. As an infant, she continually soiled diapers and subsequent control of bowel function could not be accomplished. Nocturnal enuresis was the only other symptom. Physical examination showed fecal soiling, an extremely large stool-filled rectum, and diminished rectal sphincter tone. Spine roentgenograms demonstrated widening and deformity of the lower aspect of the sacrum (Fig 1, left). The sacral defect was the only congenital defect; maternal history was negative for diabetes. Roentgenogram after barium enema showed anterior displacement of the rectum (Fig 1, right). B mode ultrasound scans demonstrated the sonolucent nature of the mass, indicative of a cystic or fluid-filled lesion (Fig 2, left). Lumbar myelography showed a large presacral meningocele (Fig 2, right). Computerized tomography (CT) demonstrated the presacral fluid-filled mass (Fig 3). Sacral laminectomy showed an anterior sacral meningocele containing lipomatous material. Microscopic examination showed adipose tissue and neural elements within the specimen consistent with a lipomeningomyelocele. Postoperatively, bowel function improved considerably, with cessation of fecal incontinence.

COMMENT

Anterior sacral meningocele is a rare entity, with only about 100 cases reported.[1] Its clinical diagnosis is particularly difficult. Identification of this entity may be elusive unless one is aware of its characteristic roentgenographic features in association with clinical history and physical findings.

The single most important roentgenographic study is the pelvic film, for detection of the characteristic lower sacral widening and deformity. The so-called scimitar or sickle appearance of the sacrum should suggest anterior sacral meningocele. If the sacrum is poorly visualized owing to overlying gas and feces in the colon, we recommend use of a pneumatic compression paddle to improve visualization.[2] Additional confirmatory roentgenographic findings are constrast studies showing displacement or compression of the rectum and myelographic evidence of anterior protrusion of the dural sac into the pelvis. Ultrasound scanning can establish its typical cys-

Fig 1.—Left, Sacral roentgenogram showing typical scimitar sacral defect (arrowheads). Right, Lateral roentgenographic view of barium enema demonstrating anterior displacement of rectum.

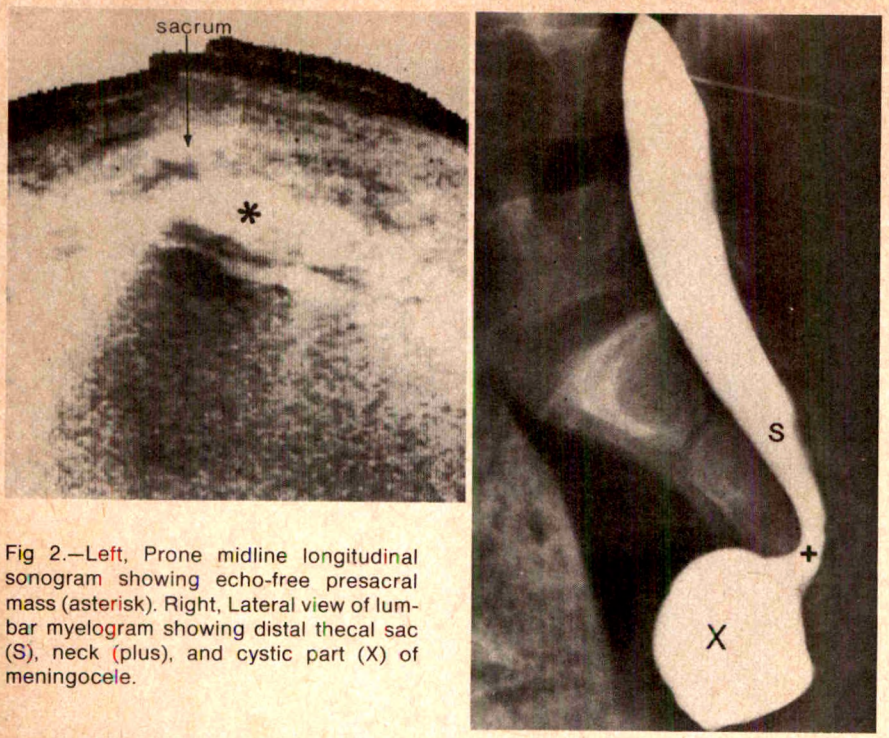

Fig 2.—Left, Prone midline longitudinal sonogram showing echo-free presacral mass (asterisk). Right, Lateral view of lumbar myelogram showing distal thecal sac (S), neck (plus), and cystic part (X) of meningocele.

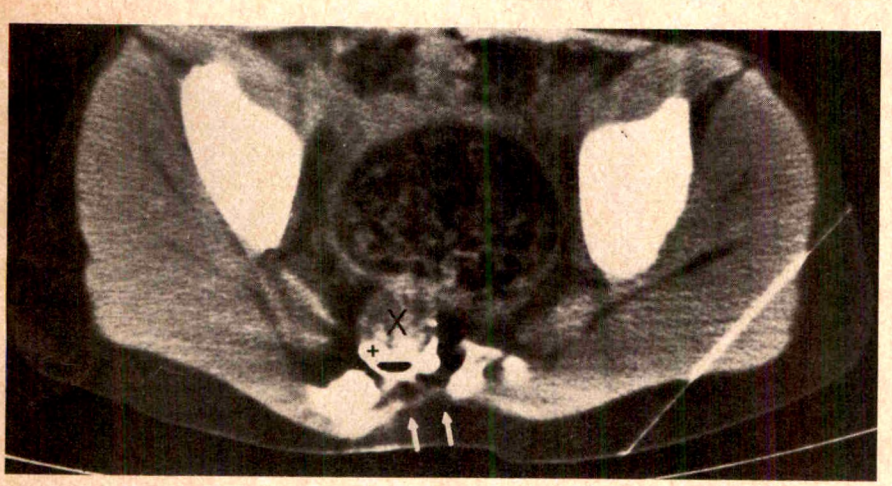

Fig 3.—Computerized tomographic scan at level of sacral defect (arrows) showing presacral mass (X) containing myelographic contrast material (plus).

tic appearance, as illustrated in this case report. If sonography is inconclusive, CT will delineate the suspected presacral mass and confirm its fluid content.

Sacral defects associated with ventral meningocele typically manifest three groups of symptoms: local pressure, local neurological deficits, and central neurological symptoms.[3] Pressure symptoms owing to the meningocele mass include constipation, urinary incontinence or enuresis, and female genital problems such as dysmenorrhea, dyspareunia, and protracted labor. Local neurological symptoms include poor sphincter control, sacral anesthesia, and lower extremity deficits. Common central neurological symptoms include nausea and headache, precipitated by straining or coughing.

In adults, anterior sacral meningocele is more common in females (86%), but the sex ratio among pediatric patients is nearly equal.[4] Age of detection has ranged from the newborn period to the eighth decade. Recent reports indicate a familial tendency;[3,5-7] an X-linked dominant gene may produce this condition.[8] Haddad's[9] review noted a 50% incidence of other congenital anomalies including spinal deformities and duplication defects of the vagina, uterus, and kidneys. Anterior sacral meningocele has been reported in association with Marfan's syndrome.[10] Differential diagnosis includes more common spinal dysraphic anomalies, presacral dermoid cyst, lipoma, chondroma, teratoma, chordoma, neuroblastoma, neurofibroma, as well as inflammatory and metastatic masses.

Surgical treatment is generally advised because spontaneous regression does not occur. The lesion is not innocuous in that deaths have occurred related to rupture of the meningocele, with resultant meningitis.[1] Irreversible nerve root damage may occur when the meningocele is not removed. There are two basic surgical approaches. Sacral laminectomy with ligation, drainage, and/or removal of the meningocele is the preferred procedure in most patients. In selected patients, low transverse abdominal laparotomy with meningocele excision is preferred.[6]

Nasal Polymorphic Reticulosis in a Child

Donald C. Houghton, MD; Eugene Blank, MD; James D. Smith, DVM, MD

• The case of nasal polymorphic reticulosis in a child is presented. The patient, an 11-year-old adopted boy, complained of nasal stuffiness and pain. Perforation of the nasal septum and ulceration of the hard palate were evident on examination, and an irregular tumor in the nasal cavity was demonstrated by tomography. Biopsy specimen showed atypical lymphoreticular cells within mixed inflammatory infiltrates. He was treated with radiation followed by cyclophosphamide, mercaptopurine, and methotrexate sodium. Despite regression of the palate lesion and a 12-month symptom-free interval, he died of disseminated polymorphic reticulosis 1½ years after diagnosis. We are unable to find a similar reported case in a child.

(*Am J Dis Child* 134:387-389, 1980)

Infiltrates of atypical lymphoreticular and mixed inflammatory cells distinguish polymorphic reticulosis from other destructive midfacial lesions.[1-3] Also known as malignant midline reticulosis, it is one of the diseases of diverse causes, which include Wegener's granulomatosis, infections and neoplasms formerly grouped under the term lethal midline granuloma. We wish to point out that polymorphic reticulosis occurs in children as well as adults.

From the Departments of Pathology (Dr Houghton), Radiology (Dr Blank), and Otolaryngology (Dr Smith), University of Oregon Health Sciences Center, Portland.

Reprint requests to Department of Pathology, University of Oregon Health Sciences Center, 3181 SW Sam Jackson Park Rd, Portland, OR 97201 (Dr Houghton).

REPORT OF A CASE

An 11-year-old boy was adopted in the summer of 1977, approximately six months before his first hospital admission. At that time, he complained of nasal pain and, at the time of adoption, had had a nasal septal perforation with heaped up tissue at the edges. A biopsy specimen one month before admission showed chronic inflammation. One week prior to admission, an ulcer of the hard palate was noted after complaints of pain after drinking orange juice. He sniffled often and had an occasional bloody nasal discharge. He had had no fever, weight loss, or decrease in activity, and he continued to play soccer.

His father died at age 33 years of unknown causes. His mother aged 35, a sister aged 8, and a half-sister aged 16 are well.

His height and weight were at the tenth percentile. He had a 2 × 2.5-cm perforation in the cartilaginous and bony nasal septum and a 2 × 1-cm ulcer of the hard palate, with surrounding granulation tissue. Palpable lymph nodes in both anterior cervical chains ranged from 1 to 3 cm in diameter. There was no hepatosplenomegaly or other lymphadenopathy. The rest of the physical examination showed no abnormalities.

His hemoglobin level was 13 g, and his WBC count was 8,000/cu mm, with 63% polymorphonuclear cells, 8% bands, 21% lymphocytes, 5% monocytes, and 3% eosinophils. Platelet count was 520,000/cu mm. The ESR was 45 mm/hr (Wintrobe). Results of urinalysis were normal. The serum albumin level was 4.3 g/dL; and the globulin level was 4.4 g. Immunoglobulin determinations indicated an IgG of 2,422 mg/dL, an IgA of 407 mg/dL, and an IgM of 131 mg/dL. The FTA-ABS and VDRL were negative. Coagulase-positive *Staphylococcus aureus* were cultured from his nose. Results of bone marrow examination were normal.

A lateral roentgenogram of the nasopharynx showed no adenoid mass. Tomograms of the face showed a large, irregular tumor in the nasal cavity (Fig 1).

The palatal and nasal aspects of the lesion were biopsied. In each specimen, the substantia propria contained infiltrates of atypical lymphoreticular cells mixed with smaller numbers of neutrophils, plasma cells, and normal-appearing lymphocytes. Eosinophils were absent. The atypical cells varied in size, most of them having moderate amounts of granular, vacuolated, lightly staining cytoplasm and poorly defined borders. Nuclei were rounded or lobed, with thick membranes. Many nuclei were vesicular, with evenly distributed chromatin and large central nucleoli. Others were folded and densely hyperchromatic, without discernible nucleoli. Mitoses were common. Neither foreign body giant cells nor Reed-Sternberg cells were identified. Infiltrates were particularly dense around vessels, and many small arteries were occluded by thrombi (Fig 2). Focal necrosis, mucosal ulceration, neutrophilic infiltrates, and nuclear debris were prominent in adjacent tissues.

Biopsy specimens of the cervical lymph nodes contained no atypical cellular infiltrates. Nodal capsules were irregularly thickened, and paracortical lymphoid tissue was hypocellular and focally fibrotic. Primary follicles were smaller and fewer than normal. Germinal centers were poorly defined; some contained hyaline-like material, others had collections of epithelioid cells resembling small granulomas. The medullae had normal architecture and cellular composition.

Shortly after the biopsy, the child's care was transferred to a medical center nearer

his home. There, the tumor was debrided, and a week later, x-ray therapy with a cobalt 60 teletherapy machine was begun. During the next 41 days, 4,448 rads were delivered to the tumor, which regressed completely.

One month later, the boy began receiving chemotherapy consisting of induction with vinblastine sulfate (Velban), prednisone, cyclophosphamide (Cytoxan), and methotrexate sodium, and maintenance with mercaptopurine, cyclophosphamide, and methotrexate. His course during chemotherapy was relatively uneventful. He appeared chronically ill, but his weight remained stable. The site of the palatal lesion remained healed, and there was no evidence of systemic disease. Lesions of herpetic stomatitis periodically appeared and resolved. Treatment was discontinued in November 1978, 11 months after it was begun, because of neutropenia and thrombocytopenia.

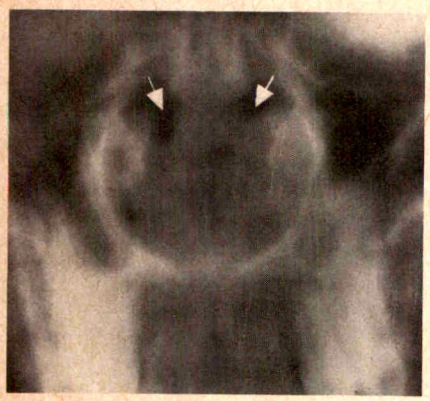

Fig 1.—Tomogram shows nasal cavity is expanded by irregular tumor (arrows). Apparent defect at bottom of bony rim is normal depression of nasopalatine recess.

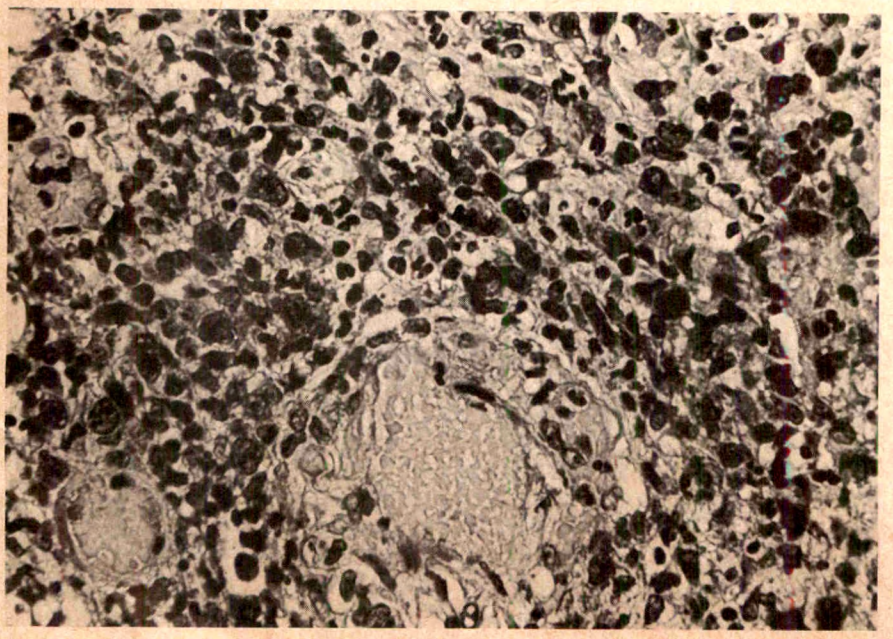
The boy was hospitalized three times in December 1978 because of recurrent hepatitis. In each instance, admission was prompted by the development of high fever, anorexia, and hepatomegaly, and on each occasion, liver function subsequently improved without specific treatment. During the first of these admissions, tests to detect viral infection were negative except for a titer of 1:640 to the Epstein-Barr virus. A screening test for heterophile antibodies was negative. A convalescent titer for Epstein-Barr virus was again 1:640.

He was hospitalized for the last time in March 1979, again with symptoms of hepatitis and cachexia. He was jaundiced and his liver edge extended 5 cm below the right costal margin. A submental lymph node had enlarged to nearly 5 cm in diameter, and smaller nodes were palpable in cervical, supraclavicular, and axillary areas. The SGOT value was 2,055 IU/L, the alkaline phosphatase level was 1,580 IU/L, and the bilirubin level was 2.4 mg/dL (0.7 mg/dL direct). His liver function improved briefly during hospitalization, but it quickly deteriorated again. After the possibility of extrahepatic biliary obstruction was excluded by ultrasonography and liver scan, the liver and submental lymph node were biopsied. Liver failure and the boy's poor general condition precluded further chemotherapy. He was discharged a month after admission and died three days later at home. An autopsy was performed.

Fig 2.—Palatal lesion showing anaplastic lymphoreticular cells and mixed inflammatory cells, including neutrophils and nuclear debris in tissue adjacent to small vessels. Vessels in lower center and lower left of micrograph are occluded by fresh thrombi; wall of larger vessel is edematous and contains a few infiltrating inflammatory cells (hematoxylin-eosin, original magnification ×680).



RESULTS

The biopsied submental lymph nodes and nearly all lymphoid tissue examined at autopsy were involved by polymorphic reticulosis. The normal follicular architecture was replaced by extensive coagulation necrosis and nodules of atypical infiltrates closely resembling those in the nasopalatal lesion. The reticulin pattern was preserved throughout the areas of necrosis. The few nodes without necrosis or abnormal infiltrates were fibrotic and generally depleted of lymphoid cells. The trabecular and vascular structures of the spleen were preserved, but the tissue was otherwise hypocellular, consisting of broad areas of fibrosis and necrosis. Sparse infiltrates of polymorphic reticulosis were evident near splenic arterioles within the remnants of lymphoid follicles. The thymus was atrophic, but it contained no atypical infiltrates.

Liver tissue obtained at autopsy, like that of the biopsy specimen, contained scattered foci of parenchymal necrosis. Many of these zones were microscopic; others were large enough to span two or more lobules without a consistent pattern of distribution. Polymorphic reticulosis cells were present within the necrotic tissue and were scattered through the liver sinusoids. Kupffer cell hyperplasia and erythrophagocytosis were particularly evident near the areas of necrosis.

Polymorphic reticulosis infiltrates and accompanying necrosis formed nodular aggregates in the subcapsular tissues of the kidneys. Atypical cells were present in tissues adjacent to shallow mucosal ulcerations in the terminal ileum.

COMMENT

The clinical features of polymorphic reticulosis are the same as those of lethal midline granuloma, first described in detail by Stewart[4] in 1933.

The course may last for several years, generally beginning with nasal stuffiness, nasal obstruction, or rhinorrhea. There may be crusting of the nasal mucosa and sinusitis. Mucosal ulceration ensues, and necrosis extends to involve adjacent bone and cartilage. The nasal discharge becomes thicker and malodorous, and there is usually pain and tenderness in the affected area. The patient often experiences fevers, malaise, and weight loss. If untreated, the lesion advances, destroying nasal and paranasal structures that may include the orbit, mouth, base of the skull, area cribrosa, and brain until death from inanition, infection, or hemorrhage results. The disease typically occurs in men in the fifth or sixth decade of life. Askin[5] stated that the lesion affects children, but to our knowledge, no cases have been reported.

Kassel et al[2] reviewed the literature of lethal midline granuloma and concluded that, except for specific infections and solid tumors, all of such cases would be in three categories: Wegener's granulomatosis, lymphoma, and polymorphic reticulosis (malignant midline reticulosis).

Histologically, polymorphic reticulosis consists of infiltrates of atypical lymphoreticular cells and mixed inflammatory cells and stellate areas of tissue necrosis. The infiltrates advance into adjacent soft tissue, bone, and cartilage, followed by necrosis and collapse. The underlying reticulin pattern is often preserved in the necrotic zones. Vessels are involved secondarily; adventitial and intimal infiltrates, endothelial proliferation, and thrombosis are often prominent. Similar vascular involvement has been described in conventional lymphomas involving the nose.[1]

The atypical cells have round or elongated nuclei with irregular or folded contours. Chromatin is usually scanty although densely hyperchromatic forms are also seen. Nucleoli may be prominent. Cytoplasmic volume is variable; cellular outlines are usually indistinct and some cells may contain phagocytized debris. These cells may form small monocellular nests, and their appearances have led in the past to diagnoses of atypical reticulum cell sarcoma and histiocytic or mixed lymphocytic-histiocytic lymphoma. Atypical cells are usually admixed, however, with lymphocytes, plasma cells, histiocytes, and polymorphonuclear leukocytes, sometimes including small numbers of eosinophils. Multinucleated cells are usually absent. This inflammatory character of the infiltrate, its loose, noncohesive growth, and the extensive necrosis help distinguish polymorphic reticulosis from most conventional lymphomas. Cells resembling Reed-Sternberg cells are not found in polymorphic reticulosis.

Wegener's granulomatosis is characterized by a combination of necrotizing arteritis, granulomatous inflammation, abundant inflammatory infiltrates including eosinophils, and the absence of cellular atypia. Most patients will also have clinical evidence of pulmonary and renal involvement. Both Wegener's granulomatosis and primary lymphomas of the nose occur in children.[6,7]

Embryonal rhabdomyosarcoma and nasopharyngeal carcinoma also cause destructive nasal lesions in children. Lack of differentiating features may leave the identity of either tumor in doubt and may prompt consideration of lymphomas or other tumors in some instances. Neither should be confused with the loose, pleocellular infiltrates of polymorphic reticulosis.

Opinions vary regarding the nature of polymorphic reticulosis and its relationship to other destructive midfacial lesions.[1,2,8-10] Despite this, authors agree that the appropriate treatment differs with each entity and that a specific diagnosis should be made even if repeated biopsies are necessary.[8,11-13]

The facial lesion of polymorphic reticulosis usually resolves after adequate radiotherapy.[11,12] Some patients, like our own, however, eventually die of a disseminated disease despite initial response to x-ray treatment.[11,14]

Joel E. Hass, MD, associate pathologist, and Ronald L. Chard, Jr, MD, Associate Director of the Division of Hematology/Oncology at the Children's Orthopedic Hospital and Medical Center, Seattle, provided important histological material and information regarding this patient's treatment and clinical course.

Friedreich's Ataxia With Acute Cardiomyopathy

Robert A. Berg, MD; Allen M. Kaplan, MD;
Paul B. Jarrett, MD; Marian E. Molthan, MD

• Friedreich's ataxia (FA) is a progressive, spinocerebellar degenerative disease. Onset is generally in the second decade of life, occurring as a neurologic degenerative process. Most, if not all, patients have an associated cardiomyopathy, which is frequently the cause of death. We studied two siblings who had FA with acute cardiomyopathy at 3 and 5 years of age, respectively, and in whom the classic nervous system signs developed, only later. The diagnosis of FA should be considered in patients of any age who have unexplained cardiomyopathy.

(*Am J Dis Child* 134:390-393, 1980)

Friedreich's ataxia (FA) is an autosomal recessive form of spinocerebellar degeneration, characterized by relentless and progressive ataxia, muscle weakness, dysarthria, sensory abnormalities, areflexia, and skeletal deformities. The onset is usually early in the second decade of life, and in most patients a slowly progressive cardiomyopathy develops. Although the cardiomyopathy is variable in its clinical occurrence and may remain asymptomatic throughout the course of the disease, cardiopulmonary sequelae are the usual cause of death in this disease. We studied two siblings with FA that had an unusual clinical course. Both, when younger than 5 years of age, initially had an acute cardiomyopathy; only later did neuromuscular disease develop. Death occurred in both children before they were 12 years old, and, at the time of postmortem studies, typical CNS and cardiac findings of FA were confirmed. The importance of considering the diagnosis of FA in any patient in whom an unexplained cardiomyopathy develops must be emphasized.

REPORT OF CASES

Case 1.—A 6-year-old girl was transferred to Good Samaritan Hospital, Phoenix, Ariz, because of refractory congestive heart failure (CHF). She had been healthy until 3 years of age, when CHF developed, and her condition was evaluated at the University of Minnesota. Diagnostic studies performed at that time included an ECG, chest roentgenograms, and a cardiac catheterization. A diagnosis of an acute cardiomyopathy was made. Her 6-year-old brother had had a similar episode of CHF one year earlier and was noted subsequently to have truncal and upper extremity ataxia. Despite the normal results on neurologic examination, both children were considered to have FA. Over the following three years, the patient had recurrent bouts of CHF that required frequent hospitalizations. Throughout this period, she continued to walk well, and her parents did not notice any neuromuscular problems. Her developmental progress was normal. There was no history of consanguinity or family history of neuromuscular or cardiac disease.

Physical examination on admission to the hospital showed a chronically ill and cachectic child. Vital signs included the following values: pulse, 124 beats per minute; blood pressure, 85/40 mm Hg; respirations, 48/min; and temperature, 37 °C. The patient had mild intercostal retractions, nasal flaring, and basilar rales bilaterally. A sinus tachycardia with a gallop rhythm was noted. The liver was palpable 5

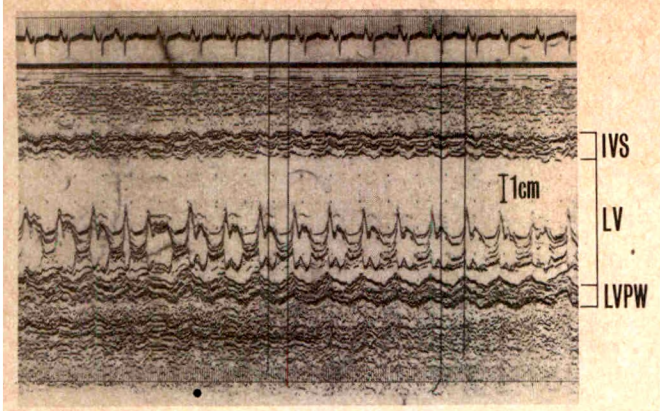

Fig 1.—Echocardiogram showing nonobstructive cardiomyopathy with evidence of left ventricular enlargement (LV) and mild hypertrophic changes of left ventricular posterior wall (LVPW) and intraventricular septum (IVS) in patient 2.

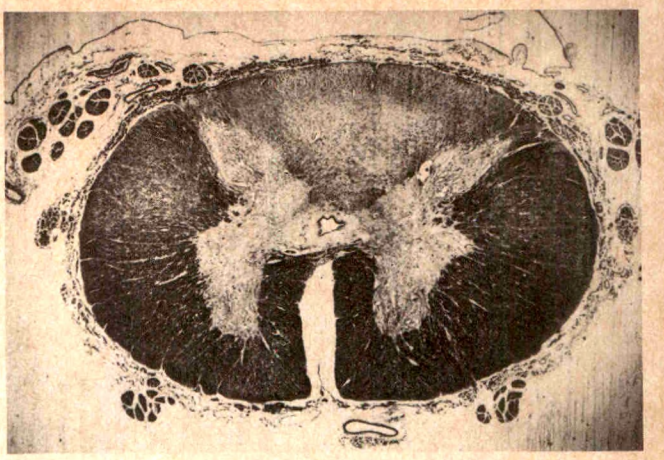

Fig 2.—Transverse section of the spinal cord showing demyelination of the posterior columns, lateral corticospinal and posterior spinocerebellar tracts, and dorsal nerve roots (luxol-fast blue, original magnification ×2.5).

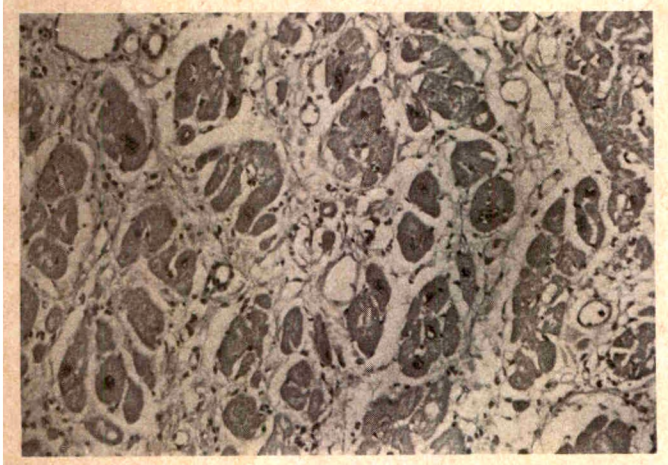

Fig 3.—Section of myocardium showing areas of focal degeneration and atrophy of muscle fibers with enlarged hyperchromatic nuclei (hematoxylin-eosin, original magnification ×40).

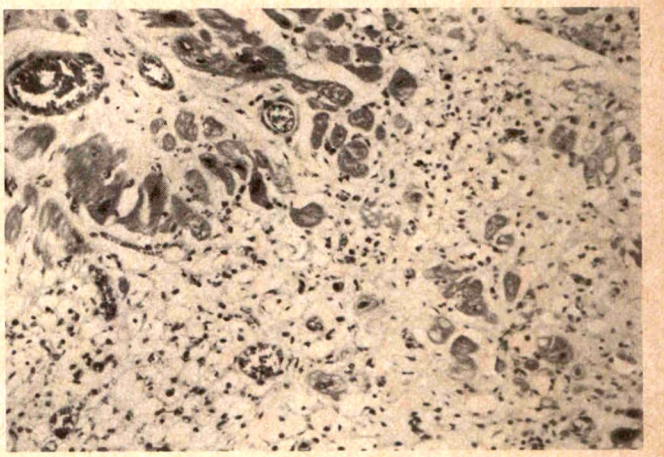

Fig 4.—Section myocardium demonstrating severe interstitial fibrosis and scattered inflammatory cells (hematoxylin-eosin, original magnification ×40).

cm below the right costal margin, and there was moderate peripheral, facial, and anterior chest wall edema. A pes cavus deformity was noted and kyphoscoliosis was present. The child was weak and had evidence of generalized muscular atrophy. Dysmetria was present, and vibratory sense was diminished. The cranial nerves were normal. The deep tendon reflexes were absent.

Results of laboratory investigations showed that complete blood cell count (CBC), results of urinalysis, and serum electrolyte levels were normal. An ECG showed sinus tachycardia, combined atrial hypertrophy, left ventricular hypertrophy, and inverted T waves. Chest roentgenograms demonstrated an enlarged heart with evidence of pulmonary edema. There were no pulmonary infiltrates.

The hospital course was characterized by progressive weakness, increasing tachypnea and persistent tachycardia, and neurologic deterioration despite medical management. The patient had a cardiac arrest and died on the second hospital day.

Case 2.—A 12-year-old boy (sibling of case 1) was admitted to Good Samaritan Hospital because of congestive heart failure. At 5 years of age, congestive failure developed, that required hospitalization and treatment with digitalis and diuretics. The cardiac symptoms resolved over several weeks and required no further medical management. At 6 years of age, his condition was evaluated at the University of Minnesota because of his sister's myocardiopathy. He was noted to have an ataxic gait, mild upper extremity intention tremor, and loss of deep tendon reflexes. There was no apparent heart disease at that time, and the child was fully active. At 10 years of age, he was noted to have scoliosis and bilateral pes cavus deformities. At age 12 years, he had a recurrence of CHF. Six months prior to his final hospital admission, progressive shortness of breath, chest pain, orthopnea, and peripheral edema developed. The ataxia worsened steadily over this six-month period, and signs of dysarthria and nystagmus developed.

Physical examination on admission to the hospital showed a thin, chronically ill, and depressed 12-year-old boy in moderate respiratory distress. His height was 155 cm; his weight, 36.4 kg. Vital signs included the following values: pulse, 100 beats per minute; blood pressure, 100/60 mm Hg; respirations, 34/min; and temperature,

Fig 5.—Photograph showing thrombosis of superior vena cava (arrow) and innominate veins.

37 °C. The examination of head and neck gave normal results except for a diffuse 3 × 3-cm, tender, nonerythematous, right supraclavicular mass. There were moderate intercostal retractions, nasal flaring, and bilateral basilar rales. A grade 2/6 systolic murmur was heard, and there was a persistent gallop rhythm. The neck veins were distended, and the liver was palpable 5 cm below the right costal margin. Peripheral pulses were weak. There were severe pes cavus deformities and moderate thoracic kyphoscoliosis. Results of examination of the cranial nerves were normal except for horizontal nystagmus. There was no optic atrophy. Vibratory and position senses were lost bilaterally, but pain and touch were intact. Generalized muscle weakness and atrophy were present. Truncal ataxia, dysmetria, and intention tremor were severe. The deep tendon reflexes were absent, and Babinski's signs were present bilaterally.

Laboratory investigations yielded a normal CBC and serum electrolyte and chemistry levels. A fasting blood glucose level was 88 mg/dL. Chest roentgenograms showed a large heart and scoliosis. Subsequent films showed persistent cardiomegaly, left pleural effusion, and bilateral nodular infiltrates. An ECG showed right axis deviation with left ventricular and right atrial hypertrophy, occasional premature ventricular contractions, and intermittent atrial fibrillation. Echocardiography showed poor myocardial contractility, severe left ventricular dilation, and prolonged systolic time intervals (Fig 1). There was no evidence of hypertrophic subaortic stenosis. Severe dilation of the left atrium was also noted. Sonography and computerized tomography of the neck demonstrated the presence of a solid mass.

The clinical course was characterized by progressive cardiac decompensation. Conventional therapy was unsuccessful, and the patient died after one month.

The autopsy findings in both siblings were virtually identical and were characteristic of FA. In the spinal cord, the posterior columns were shrunken and degenerated, as were the dorsal nerve roots. Atrophy of Clarke's columns and the posterior spinocerebellar tracts was virtually complete in the thoracic cord. The pyramidal tracts showed progressive fiber loss as they descended, and degeneration of the fasciculus gracilus and cuneatus was noted. The degenerated tracts were gliotic, with myelin loss visible macroscopically (Fig 2). Sections of the pons and the medulla showed diffuse loss of cells in the pyramidal tracts, and there was mild dropout of Purkinje's cells within the cerebellum. The cerebral hemispheres were normal.

The lesions in the heart were also identical, demonstrating a prominent cardiomyopathy with severe replacement of the myocardium with collagen and secondary mural thrombi. Areas of focal degeneration of muscle fibers with enlarged hyperchromatic and frequently bizarre nuclei were characteristic (Fig 3). There was no evidence of coronary vascular abnormalities, and no abnormal calcifications were noted. Interstitial fibrosis in many areas was severe, and scattered round cell infiltrates were seen as a response to active degeneration of myocardial fibers (Fig 4). There was extensive thrombosis in the pulmonary venous system and superior vena cava and its tributaries (Fig 5), the latter resulting in a large neck mass.

COMMENT

Friedreich's ataxia was first described in 1861[1] and is the most common of the hereditary ataxias. Neuropathologic studies performed in the early 1900s defined this disease more clearly, but there has been little progress made toward understanding the cause and pathogenesis of FA, despite more recent clinical, biochemical, and neuropathologic investigations. In many patients, glucose intolerance and diabetes mellitus develop.[2-4] Several investigators have demonstrated mild hyperbilirubinemia, slow pyruvate oxidation, elevated serum and urine alanine levels, low CSF taurine and aspartic acid levels, elevated levels of urine taurine, and elevated levels of urine β-alanine and β-aminoisobutyric acid,[4,5] but these changes are not seen in all patients with FA.

Clinical criteria for the diagnosis of FA have been established[6] and include the following: (1) autosomal recessive inheritance, (2) onset before the end of puberty, (3) progressive and relentless ataxia without remission and usually accompanied by muscle weakness, (4) dysarthria, (5) absent or severe decrease in vibratory and/or position sense, (6) absence of deep tendon reflexes in the lower limbs, (7) progressive development of pes cavus and kyphoscoliosis, and (8) progressive cardiomyopathy. Electromyography and motor nerve conduction rates are normal, but sensory nerve conductions (evoked potentials) are diminished or absent. Intellectual impairment, nystagmus, deafness, vestibular signs, optic atrophy, and autonomic dysfunction are variably present.

Cardiac involvement in FA has been well documented and was recognized pathologically in three of the initial six cases described by Friedreich.[1] Most patients ultimately show evidence of cardiac involvement on clinical studies, roentgenograms, or ECGs.[2-4,7-10] Echocardiography is a useful technique in evaluating the severity of cardiac involvement and provides a sensitive means for the diagnosis of hypertrophic cardiomyopathy.[11] Hewer,[8] in a review of 27 fatal cases of FA, found that over 50% died of cardiac complications and that 75% had evidence of cardiac involvement during life. The cardiomyopathy is often present and asymptomatic at the onset of the illness and may not cause symptoms until late in the course of the disease. It does not seem to correlate with the severity of the neurologic signs. Severe cardiomyopathy early in the course or prior to the onset of neurologic signs occurs, but is distinctly unusual.[12] Brusca et al[13] in 1965 also stressed that cardiac involvement may be the sole expression of the disease in some instances. The cardiomyopathy is degenerative in type and seems unrelated to electrolyte disorders, hypoglycemia, endocrine dysfunction, infectious agents, or coronary vascular disease. Widespread small coronary vessel involvement has been inconsistently noted at necropsy,[14] and medial thickening of cardiac arterioles associated with arteritis and endothelial proliferation has been described. This, however,

does not seem to be a primary etiologic factor in the development of the cardiomyopathy.[9]

Electrocardiographic changes occur in most patients with FA,[2-4,7,8] and Thoren[10] in 1964, studying 49 patients, showed a 92% incidence of abnormal tracings. Electrocardiographic abnormalities documented in these studies include atrial fibrillation, varying degrees of heart block, ventricular tachycardia, T-wave flattening or inversions, nonspecific ST-T-wave changes, and atrial and ventricular hypertrophy.

Sanchez-Casis et al[7] in 1976 reviewed the cardiac pathology seen in FA. The most constant finding was macroscopic cardiomegaly with some degree of ventricular hypertrophy. Atherosclerotic plaques involving major branches of the coronary arteries were also noted but were not considered to be of hemodynamic significance. Histologic changes included diffuse myocardial fibrosis, most preponderant in the anterior wall of the left ventricle and septum, and focal degeneration of cardiac muscle fibers. One additional finding not previously described was the presence of granular deposits of calcium and iron within muscle cells. In view of these abnormalities, the authors concluded that "a cardiomyopathy, hypertrophic in type and occasionally obstructive, appears to be an integral part of Friedreich's ataxia."

More recent reports have suggested an association between the cardiomyopathy of FA and idiopathic hypertrophic subaortic stenosis (IHSS).[11,15,16] Smith et al,[11] reviewing 11 patients with FA, found one third to have evidence of hypertrophic cardiomyopathy (HCM) by echocardiography, with two of these patients showing clinical features of left ventricular obstruction typical of IHSS. The authors, therefore, suggested that "HCM is the specific cardiomyopathy of classical FA and that both the neurologic and myocardial defects represent pleiotropic effects of the same deleterious gene."

The treatment of FA is unsatisfactory, and no specific therapy is available. In view of the substantial number of cases with associated cardiomyopathy, early recognition and treatment of this complication may favorably influence the prognosis. Congestive heart failure secondary to the cardiomyopathy is generally treated with digitalis and diuretics, although in the occasional patient with obstruction to the left ventricular outflow, digitalis may not be beneficial. The abnormalities seen on ECGs (ST-T–wave changes) from patients with FA seem to be consistent with increased calcium flux into the cardiac muscle cells. Therefore, agents that decrease this mechanism will reduce heart rate, decrease myocardial oxygen demand, and increase cardiac efficiency. Increased taurine intake and administration of verapamil reduce calcium influx and may be useful in modifying the cardiomyopathy or preventing its progression.[9] These latter drug approaches, however, need further investigation.

Our patients had an unusual presentation of FA in which acute cardiomyopathy with congestive heart failure occurred in early childhood without initial neurologic abnormalities. The classic neurologic symptoms and signs of FA developed only later. The children died, with evidence of severe chronic cardiomyopathy, at 6 and 12 years of age, respectively. There was no evidence of hypertrophic subaortic stenosis. In addition, these patients had unusual edema of the anterior chest wall and neck, which at postmortem examination was found to be secondary to venous thrombosis of the superior vena cava and its tributaries. This was presumably secondary to poor myocardial contractility and venous stasis. In view of our patients' presentation, we stress the need to consider the diagnosis of FA in patients of all ages who have acute cardiomyopathy of unknown cause. Careful history and neurologic and skeletal examinations in children with unexplained heart failure may lead to an early diagnosis of FA.

Bilateral Carpal Tunnel Syndrome in an Adolescent

Mark H. Feingold, MD; Ernest Hidvegi, MD; Samuel J. Horwitz, MD

• A 13-year-old boy with nocturnal paresthesias of the hands was shown to have bilateral carpal tunnel syndrome by electrodiagnosis. Surgical findings included thickening of the transverse carpal ligament and local anomalies of tendon and muscle. Surgical correction produced prompt relief.

(*Am J Dis Child* 134:394-396, 1980)

Carpal tunnel syndrome (CTS) is a peripheral entrapment neuropathy of the median nerve caused by localized pressure on that structure as it courses beneath the flexor carpal retinaculum. A common disorder of adults, it is distinctly unusual during childhood. We studied a case of bilateral CTS with onset in adolescence.

REPORT OF A CASE

The patient, a 13-year-old boy, had been in good health until eight months earlier, when he began to be awakened by late nocturnal pain and numbness. He also complained of "pins and needles" and "burning" in both hands, specifically affecting the thumbs, index and middle fingers, and lateral side of the ring fingers. He obtained some relief by shaking or wringing his hands and could then return to sleep. He complained of no weakness, pain, or loss of feeling during the daytime hours. Three months before his symptoms began, he had started weight lifting and riding a minibike, but had operated no other power equipment. His symptoms were aggravated after certain daytime activities, such as shoveling snow or writing a great deal. Only his mother was available to provide a family history, and she was unaware of similar symptoms in any relatives. The patient's statural growth had been normal, and puberty had begun at 11 years of age. His history was noncontributory, except for a probable viral illness one year prior to onset of his hand symptoms. This illness had been manifested by generalized weakness and myalgia, abdominal pain, fever, scleral injection, and transient proteinuria. Extensive evaluation at that time failed to show a specific cause, and his symptoms were fully resolved after one month. An asymptomatic, nonossifying fibroma of the proximal metaphysis of the right femur was discovered incidentally, when the patient bruised his knee. There had been no other skeletal complaints or findings.

Physical examination showed a robust, muscular boy with a height of 161 cm (75th percentile) and a weight of 68 kg (97th percentile). Blood pressure was 134/55 mm Hg supine. Physiognomy was normal, and puberty was estimated at Tanner's stage 3-4. Many freckles were present, but there were no neurocutaneous lesions. The joints all had full range of motion. The arms and hands were symmetric, and there was no atrophy of the thenar eminences. Finger strength was normal, and he was able to perform full-length pushups with weight supported on the outstretched fingertips. Sensory examination, including light touch, pinprick, position and vibratory senses, graphesthesia, two-point discrimination, and stereognosis, was entirely normal. Tinel's sign (pain on tapping of the median nerve along its course at the wrist) and Phalen's sign (hand pain and paresthesia after acute volar flexion at the wrist) were absent. The radial pulses were equal and normal. The results of the remainder of the neurological examination were normal, including tests of affect, intelligence, cranial nerves, motor strength, cerebellar function, and deep tendon and superficial reflexes.

Roentgenograms of both wrists were normal. Other studies with normal results included complete blood cell count, urinalysis, and BUN, random glucose, serum thyroxine, uric acid, cholesterol, protein electrophoresis, immunoelectrophoresis, folic acid, and vitamin B_{12} levels.

Needle electromyography (EMG) was carried out in the left pronator teres, flexor carpi radialis, flexor carpi ulnaris, first dorsal interosseous, and in the abductor pollicis brevis muscles bilaterally. Only the abductor pollicis brevis showed an abnormality, which consisted of increased insertion activity with "pseudomyotonic" bursts and spontaneous fibrillations; voluntary muscle contraction showed mild reduction

Operative findings, right hand.

in number of motor units firing, although the individual motor units were normal in pattern. Motor conduction velocity along the median nerve from elbow to wrist was normal, whereas the time required for a stimulus at the wrist to reach the abductor pollicis brevis in the thenar eminence (median motor nerve distal latency) was greatly prolonged. Transmission time for a stimulus delivered to the index finger to reach the wrist proximal to the carpal tunnel (median nerve distal sensory latency) was so impaired as to be unrecordable. Amplitude of the muscle action potential of the abductor pollicis brevis resulting from stimulation of the motor fibers of the median nerve proximal to the carpal tunnel was abnormally low, which indicated nerve demyelination. These electrodiagnostic findings confirmed the presence of entrapment of the median nerve at the carpal tunnel (Table). Motor and sensory distal latency studies of the mother's left median nerve were normal.

Early operation was undertaken with similar findings in each hand. The transverse carpal ligaments were extremely well developed, measuring 4 to 6 mm in thickness, with a rubbery, fibrotic consistency. The palmaris longus tendon was abnormally thickened and had abnormal tendon slips that inserted into the palmar aponeurosis. The parts of the palmaris brevis muscle that arose in the transverse carpal ligament were abnormally thickened. These muscle fibers appeared to be densely woven into the ligament in such a way as to create a pseudotunnel overlying the median nerve. Both median nerves had a swollen, fusiform shape, measured 22 mm wide, and appeared to be ischemic. On the anterior surface of each nerve, just beneath the proximal edge of the thickened transverse carpal ligament, there was a constriction groove. Bilateral carpal tunnel release procedures were carried out with sectioning of the transverse ligaments and release of the abnormal tendon slips (Figure). Postoperatively, the patient has had no sensory discomfort and has retained excellent strength in both hands ten months after surgery. Five months after operation on the right wrist and two months after operation on the left wrist, electrodiagnostic studies showed improvement (Table).

COMMENT

The CTS was delineated in the 1940s as a clinical syndrome due to pressure on the median nerve within the confines of the carpal tunnel.[1,2] In contrast to many large series that describe this syndrome in adults and account for thousands of cases,[3-5] we found only 29 cases in childhood reported to date.[6-20] In a recent study of 1,215 patients, none was younger than age 16 years.[21]

The carpal tunnel is formed posteriorly by the proximal row of carpal bones, and anteriorly by the transverse carpal ligament. Coursing through this tunnel are nine tendons, their sheaths, and the median nerve. The palmaris longus tendon passes anterior to the transverse carpal ligament, but partially inserts into that structure. The palmaris brevis muscle originates from the transverse carpal ligament and extends medially to insert into the skin of the hypothenar eminence. Compression of the median nerve within the carpal tunnel creates a syndrome that affects the thumb, the index and middle fingers, and lateral side of the ring fingers, those digits having median nerve sensory innervation. Patients are regularly awakened from sleep by pain, numbness, burning, or tingling, which is gradually relieved by wringing or shaking the affected hand. Physical examination may show objective sensory deficits of the median nerve sensory distribution and Tinel's and/or Phalen's signs are often present. Median motor nerve involvement may produce early weakness of thumb abduction and opposition (abductor pollicis brevis and opponens pollicis),[5] and later, atrophy of the thenar eminence with severe functional deficits. In the majority of cases, however, objective clinical findings do not develop for months, or even years. Our patient had a typical history of nocturnal hand paresthesias, but normal results from physical examination of his hands. Accurate and early diagnosis was achieved by nerve conduction and EMG studies.

It seems generally agreed that, among adult patients, thickening of the transverse carpal ligament is neither present with nor a cause of CTS.[3,21-23] Several reports of CTS in children, however, describe significant thickening of this ligament in otherwise healthy children,[12-15] and a familial incidence of CTS associated with thickened transverse carpal ligament has been described.[12] In adults, both those with and without CTS, the transverse carpal ligament has been found to be 2.0 to 3.6 mm thick,[23] much less than the 4 to 6 mm measured in our patient. Unfortunately, we were unable to explore the possibility of a familial disorder.

Other local factors that have been reported to cause CTS in childhood include trauma,[9,10] congenital anomaly,[8] hemangioma,[24] tendon calcification,[16] mucopolysaccharidosis,[18] and mucolipidosis.[17] Taylor[5] has reviewed the many and varied causes of CTS in adults, but the majority of adult cases seem to be idiopathic. The role of occupational stresses has been postulated,[5] and it may be that weightlifting or riding a minibike served to precipitate symptoms in this boy. No evidence of systemic disease was found in our patient. Local anomalies of the palmaris longus tendon and of the origins of the palmaris brevis muscle, in addition to the impressive thickening of the transverse carpal ligament, were the basis for his problem.

After surgery, our patient's median nerve motor and sensory distal latencies improved, and the amplitude of the motor nerve action potentials increased, reflecting improved function of the distal median nerve and confirming the benefit afforded by early operative care.

Temporizing, nonsurgical treatments such as splinting and local injection of corticosteroids, often suggested for adult patients, would seem to us to have no indications in a child or adolescent when an unequivocal diagnosis of CTS has been established by electrodiagnostic studies.

Review

Essential Fatty Acids Revisited

Zvi Friedman, MD, FRCP(C)

Polyunsaturated fatty acids (PUFAs) are aliphatic monocarboxylic acids with two or more double bonds in any positional arrangement or geometric configuration. Those PUFAs that prevent or relieve the symptoms of dietary deficiency in humans and animals are named, therefore, the essential fatty acids (EFAs).

The EFAs are a group of naturally occurring unsaturated fatty acids of chain length 18, 20, or 22 carbon atoms and they contain between two and six methylene interrupted double bonds in cisconfiguration. The fatty acids are essential to the diet of man and all higher animals as they cannot be synthesized de novo from other lipids or from carbohydrates and amino acids. There are two fundamental EFAs, linoleic and α-linolenic acids, from which all others are derived metabolically.[1] The essentiality of the PUFAs is related to their capability to incorporate into lipids and to act as a precursor in the formation of prostaglandins.

Historically, the essentiality of dietary fat was first demonstrated in 1929 by Burr and Burr[2] who observed poor growth and skin lesions in rats raised on a fat-free diet, symptoms that could be prevented by the administration of dietary linoleic acid.

PUFA METABOLISM

Earlier studies have established that linoleate, linolenate, oleate, and palmitoleate each serve as the initial unsaturated precursor for the biosynthesis of an independent family of PUFAs.[3] The biosynthetic pathways, as depicted in Fig 1, consist of a series of desaturation and chain elongation reactions in which there is no direct crossover between unsaturated metabolites from one sequence to the other.[3]

Although no conversions take place between the member fatty acids of different series, inhibitions and competition between fatty acids within these different series have been demonstrated. Several studies[4,5] have suggested that linoleate and linolenate compete for a common system of enzymes that elongate and desaturate the molecules to produce their higher-homologue, unsaturated derivatives. This competition can be displaced in either direction, and the acid favored in this competition is dependent on the relative dietary levels of these acids.

In addition to the competitions between the PUFAs, the more saturated dietary fatty acids also influence the PUFA content of tissues. Enhanced EFA deficiency in the presence of saturated fat has been documented.[6] On diets in which EFA content is marginal, low caloric intake and slow growth result in less severe deficiency than high intake and rapid growth. It seems that the EFAs are necessary for the proper use of the saturated fatty acids and to promote growth.[2]

METABOLISM IN EFA DEFICIENCY

Competitive feeding studies and enzymatic experiments suggest that a common enzyme may further desaturate oleate, linoleate, and linolenate. The affinity of the ω3 and ω6 acids for the enzyme system is higher than ω9 and ω7 acids (ω notation signifies the position of the first double bond numbered from the methyl terminus of the acid). Thus, under normal dietary conditions, when linoleate is included, linoleate and oleate compete for the same desaturase; and in this way, the desaturation of oleate is inhibited or blocked. This inhibition is the rate-limiting step in the biosynthesis of Δ-5,8,11-eicosatrienoic acid (20:3ω9). Conversely, when the diet is devoid of the EFA linoleate, not only is the higher homologue of linoleate, arachidonate, decreased, but the synthesis of Δ-5,8,11-eicosatrienoic acid is no longer inhibited competitively. This latter acid has been observed to increase consistently in EFA-deficient animals[7] and humans.[8]

Holman et al[9] noted that EFA deficiency resulted in a higher ratio of triene to tetraene fatty acids in several tissues of animals. A ratio of trienoic-tetraenoic fatty acids of more than 0.4 is regarded as critical evidence for EFA deficiency. Elevations of the monoenoic acids oleate and

palmitoleate also are common findings during EFA deficiency.

PUFA BIOLOGIC ACTIVITY
Role in Phospholipids

The physical properties of PUFAs differ in many ways from those of long-chain saturated fatty acids. The essential fatty acids are principally found in phospholipids, and so they have an accepted structural function in lipoproteins of cell membranes and enzymes.[10] Naturally occurring phospholipids generally exist in anisotropic liquid crystal states that determine the ultimate biological properties of membrane fluidity, ionization, and counterion binding affinity.[10-12] Variation in the acyl-chain saturation is the most common determinant of membrane fluidity in nature. Saturated acyl chains form highly ordered membranes in which fluidity is low. Conversely, phospholipids with unsaturated acyl chains form disordered membranes in which fluidity is high.

The ingestion of PUFAs by man have been shown to reduce plasma cholesterol[13] and triglyceride concentration[14] and to increase their proportion in lipoprotein lipids.[15]

Precursors of Prostaglandins and Thromboxanes

Prostaglandins are a group of naturally occurring lipids formed in most tissues from PUFA precursors by a microsomal enzyme system.[16] Prostaglandins and thromboxanes are not stored but are synthesized on demand after an appropriate stimulus, immediately released, and rapidly metabolized. Prostaglandins and thromboxanes have been implicated in numerous physiologic and pathophysiologic processes in every organ system in the human.

PUFA: ROLE IN INFANT NUTRITION AND METABOLISM
Placental Transfer and Cord Blood PUFA

Normal growth of infants is dependent on an adequate supply of essential fatty acid.[17] The human fetus, like the adult, is unable to synthesize the essential fatty acids, which must therefore be derived from the maternal circulation and pass through the placenta. Previous reports,[18,19] including ours,[20] confirmed the observations that maternal plasma lipid levels are elevated during pregnancy and that these levels are substantially higher than in the neonate. However, the relationship of maternal nutrition during pregnancy to fetal plasma lipid levels remains controversial. Hansen et al[21] found no correlation between maternal nutrition during the third trimester and serum lipid values of their infants. Churchill et al,[22] however, noted lower IQs in children whose mothers had biliary tract disease during gestation, and they speculated that this could be related to decreased availability of linoleic acid for fetal brain development. We[20] showed no change in cord plasma phospholipid, cholesterol ester, triglyceride, and free fatty acid concentrations through gestation.

Furthermore, no differences in the fatty acid composition of these lipid classes were found in cord venous and arterial plasma obtained from 32 infants at birth.[20] The fatty acid composition of cord plasma phospholipids at different gestational ages is shown in Fig 2. Their gestational age varied from 24 to 44 weeks, and all were normally grown infants. The concentration of linoleic acid in cord plasma phospholipid was less than half that of the maternal value. The lowest levels

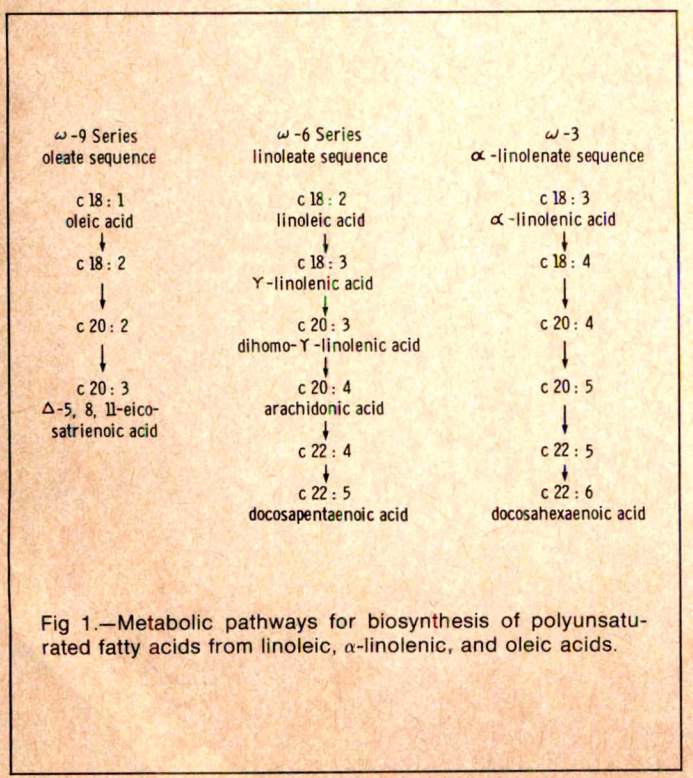

Fig 1.—Metabolic pathways for biosynthesis of polyunsaturated fatty acids from linoleic, α-linolenic, and oleic acids.

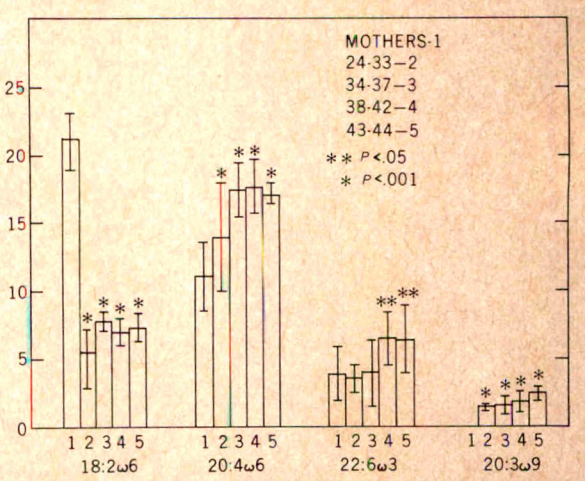

Fig 2.—Percent fatty acid composition of plasma phospholipids of mothers and their infants born at varying gestational ages. Note that relative percent of linoleic acid (18:2ω6) is lower in cord plasma phospholipids than in maternal plasma; however, levels of arachidonate (20:4ω6), docosahexaenoic acid (22:6ω3), and Δ-5,8,11-eicosatrienoic acid (20:3ω9) are higher in cord plasma than maternal plasma. Relative percent of latter acids increased with advancing gestational age. Ranges in key refer to gestational ages expressed in weeks.

of this fatty acid were noted before 34 weeks' gestation. However, venous and arterial cord plasma contained higher concentrations of the more unsaturated fatty acid, arachidonate, than did maternal plasma.[18-20] The concentration of docosahexaenoic acid, which is a homologue of the α-linolenic acid series, was noted to be higher in cord blood plasma at term as compared with maternal levels.[18-20] The increased combined total of the linoleic acid series in plasma phospholipid correlated well with the tissue levels of these fatty acids.[20]

Bruce and Svennherholm[23] reported a continuous increase in the relative concentration of fatty acids of the linoleic series in skeletal muscle phosphoglycerides, from 10% at the beginning of the second trimester of gestation to almost 50% at the age of 1 year. The increased concentration of the polyenoic fatty acids, derivatives of linoleic and α-linolenic acids, may result from the increased activity of the fetomaternal unit by preferential transfer of these fatty acids in later gestation or from enzymatic activity in the placenta or the fetus that may be responsible for desaturation and elongation of these EFAs.[24]

In the anesthetized primate, injection of labeled linoleic and palmitic fatty acids into the mother led to their rapid appearance in the fetal circulation.[25] Dancis et al[26] demonstrated the transport of free fatty acid from the maternal to the fetal side and from the fetal to the maternal side of the isolated human placenta. Selective transport of linoleic acid across the placenta was reported in the guinea pig[27]; but in this species, the fraction of linoleic acid in plasma free fatty acids is greater in the fetus than in the mother; this is contrary to the findings in the human. Fatty acid composition of adipose tissue triglycerides in the newborn infant also differs from that of the mother[28] in the same manner as that of plasma lipids. Because of the low concentration of linoleic acid in fetal adipose tissue, its contribution to fetal plasma free fatty acid composition during lipolysis is small.

The relative percentage of the fatty acid Δ-5,8,11-eicosatrienoic acid was found to be higher in cord plasma of all infants than in maternal plasma and the level seems to increase with advanced gestation (Fig 2).[18,20,29] Although this abnormal fatty acid is elevated in EFA deficiency, such a diagnosis is not certain at the time of birth since the polyenoic acids of the linoleic acid series may be higher in the newborn infant than in the mother, yet the possibility is not eliminated that the infant may have a relative lack of EFAs. Furthermore, an increased Δ-5,8,11-eicosatrienoic acid level may reflect a generalized increase in desaturation and/or elongation of fatty acid chains in the developing fetus.

Tissue PUFA Composition

Body stores of EFAs are low in low-birth-weight infants.[30] The concentration of linoleic acid in fetal tissue is less than that seen in adults,[31] and the proportion of linoleic acid in muscle phospholipids is found to increase with advancing gestational age.[23]

We have analyzed (unpublished data, December 1978) various tissue samples from 25 human fetuses and newborns for the relative concentration of the fatty acids in phospholipids, cholesterol ester, triglycerides, and free fatty acids. Their gestational ages ranged from 16 to 44 weeks. Representative tissue from kidney medulla and cortex is shown in Fig 3. No differences are observed between the levels of the individual EFAs, linoleate and arachidonate, in the different tissues beyond 16 weeks of gestation. However, the level of arachidonate in the various tissue phospholipids is considerably elevated as compared with the level of linoleic acid. Linoleate and arachidonate cord plasma values are a reflection of their tissue levels. Both show a reduced linoleate

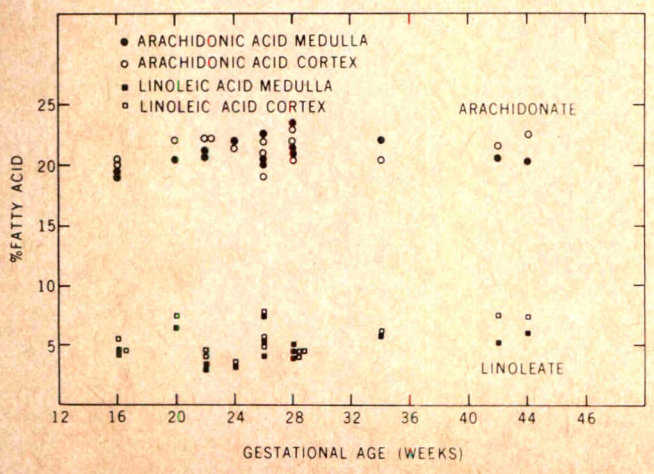

Fig 3.—Percent fatty acid composition of renal phospholipids in neonates at various gestational ages. No changes are seen between levels of linoleate and arachidonate in renal tissue beyond 16 weeks of gestation.

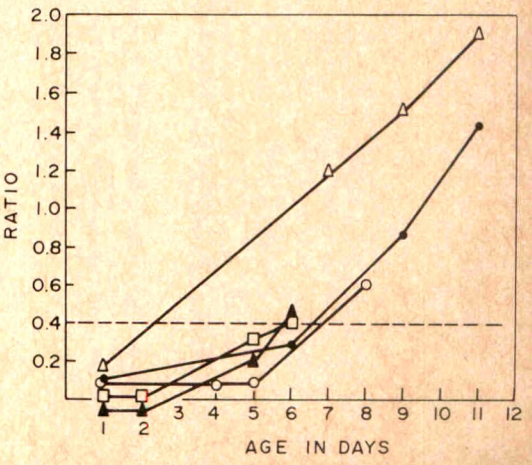

Fig 4.—Ratio of Δ-5,8,11-eicosatrienoic acid to arachidonic acid in plasma phospholipids during fat-free diet. Dotted line signifies normal ratio. Open and solid triangles, open and solid circles, and open square each represent a different neonate (from Friedman et al[29]).

level compared with the maternal level; however, the higher homologue, arachidonate, is higher than the maternal value. The low plasma concentration of linoleate reflects the reduced tissue level of this fatty acid.

This situation increases the maternal-fetal gradient for linoleic acid that may facilitate its transfer across the placenta. Tissue enrichment in arachidonic acid may play an important role by maintaining the normal function of biological membranes and by serving as a substrate for prostaglandin biosynthesis. These functions may influence fetal physiology during intrauterine development.

After birth, the diet affects the fatty acid composition of adipose tissue. In the period of rapid weight gain, during early infancy, changes in adipose tissue composition can occur in a relatively short time.[32] Recently, Widdowson et al[33] demonstrated a profound difference in the fatty acid composition of adipose tissues between British and Dutch infants in the first year of life. The differences were influenced directly by the nature of the fat in the diet.

EFA Deficiency Syndrome

Clinical Manifestations Associated With Oral Diets.—Work with experimental animals showed that the extremely young are more susceptible to EFA deficiency owing to lack of fat in the diet than are adults.[34] Similarly, body stores of EFAs are low in low-birth-weight infants, which results in the deficiency state becoming evident more rapidly than in an adult. Most of the earlier studies that have been performed on humans included infants. These studies, which started as early as 1919 by Von Gröer,[35] showed the effects of diets low in fat on growth or weight loss,[35] susceptibility to infection,[35,36] and skin eruption.[36] The observation that skin lesions in rats fed a low-fat diet were cured by the addition of fats rich in PUFAs stimulated clinical studies in infants and children with chronic eczema.[37] Their diets were supplemented with oil containing PUFAs and were noted to induce a substantial clinical improvement that was associated with increasing iodine values to the same range as for control subjects. These results were encouraging enough to warrant further studies to evaluate the role of unsaturated fatty acids in human nutrition.

Hansen et al[17] fed 428 healthy infants one of five proprietary milk mixtures adequate in protein, minerals, and vitamins but varying in linoleic acid content from 0.1% to 7.3% of the calories. Two of the milk mixtures were found to contain inadequate amounts of linoleic acid for the infant's requirements. One was low in fat (1.0% of calories), and one contained fat low in linoleic acid content. A high proportion of babies who were fed the latter two milk mixtures before 6 weeks of age and who remained on the diets for 3 months had dry, thick, desquamated skin develop and their growth was retarded. The clinical manifestations disappeared after the administration of diets that provided 1% or more of the calories as linoleic acid.

Further studies[38] demonstrated that infants do not usually show overt signs of fat deficiency until they have been receiving cow's milk formula for about two months. The clinical syndrome of linoleic acid deficiency appears as inefficient somatic growth in spite of adequate caloric intake, together with skin lesions. These manifestations showed a dramatic response to a diet containing linoleic acid.

Increased basal metabolic rate in rats with linoleic acid deficiency was documented by Wesson and Burr[39] in 1931. In infants fed diets low in linoleic acid, increased caloric consumption was reported by Adam et al.[40] In spite of the differences of 20% to 40% in caloric intake between the infants fed diets low in linoleic acids and infants fed diets supplemented with linoleic acid, weight curves were similar for the majority of infants.

Clinical Manifestations Associated With Parenteral Nutrition.—The provision of optimal nutrition for low-birth-weight infants, for infants with congenital anomalies of the gastrointestinal tract, and for those with inflammatory bowel disease remains an important problem. Recently, total parenteral nutrition (TPN) has been established as a form of therapy for these conditions.[41] The development of reliable procedures for intravenous (IV) alimentation has emphasized preparations consisting of dextrose, amino acids, minerals, and vitamins; and recently, attention has been focused on PUFAs.

Recently, Collins et al[42] described EFA deficiency induced by prolonged administration of fat-free IV infusion in a 44-year-old man. The biochemical manifestations of EFA deficiencies were accompanied by dermal symptoms. Both the clinical and biochemical changes were corrected when linoleic acid was given in the form of fat emulsions. Similar studies of infants whose conditions were maintained by long-term, fat-free parenteral nutrition demonstrated the development of clinical signs together with biochemical evidence of EFA deficiency.[43,44] The administration of diets containing linoleic acid converted these clinical and biochemical manifestations to normal.

We studied[29] five sick newborns whose conditions were maintained by fat-free IV alimentation and who had extremely rapid biochemical changes in the plasma develop that were compatible with the diagnosis of EFA deficiency during the first week of life and that were reversible with oral feedings containing EFA. The youngest and the smallest infants exhibited these changes as early as the second and third days of life (Fig 4).

The body of a premature infant weighing 1,000 g contains approximately 0.5% glycogen, 1% fat, and 8.5% protein.[30] In such an infant, the total caloric reserve is 450 calories/kg, and the nonprotein caloric reserve is only 110 calories/kg. The minimal metabolic requirement of an infant of this size is about 30 to 40 calories/kg/24 hr in the first day of life, and it increases to 45 to 50 calories/kg/24 hr thereafter. With increments for activity, stress of hypothermia or hyperthermia, asphyxia, infection, etc, the total caloric expenditure is probably in the order of 50 to 75 calories/kg/24 hr.

Because of the limited nonprotein caloric reserve, these infants must

mobilize fatty acids early for caloric needs when faced with deficient dietary intake. Thus, the borderline stores of EFA characteristic of the premature and the high caloric expenditure in these infants may contribute to the early onset of EFA deficiency that we observed among premature infants receiving fat-free parenteral feedings. Furthermore, during parenteral alimentation, the outflow of linoleic acid from adipose tissue is blocked, at least in part, by the high blood insulin levels accompanying dextrose administration. During fat-free IV alimentation, there is a correlation between EFA deficiency in plasma and that in tissues.[44] Similar correlation has not yet been demonstrated in cases with rapid onset of EFA deficiency.

Absence of EFA from the diet has been associated with a specific syndrome of deficiency in young animals and infants. For a complete description, the reader is referred to several published reports.[1,34] The syndrome includes the following: (1) diminished growth[2,17]; (2) dermatitis[2,17,44,45] (Fig 5), diminished skin pigmentation, caudal necrosis,[2] and loss of muscle tone[46]; (3) anatomical and degenerative histologic changes in the kidney,[2] lung,[47] and fatty liver[48]; and (4) physiologic changes that include impaired reproduction,[49] increased basal metabolic rate,[39,50] increased permeability of skin, impaired water balance,[39,49] increased fragility and permeability of cellular membranes associated with changes in intracellular membranes,[51,52] ECG changes,[53] lowered resistance to radiation injury,[54] and atherosclerotic changes.[55]

Effect on RBCs.—Fatty acid composition of RBC changes in relation to dietary linoleate as it does in plasma, but the changes occur more slowly. Farquhar and Aherens[56] suggested the evaluation of fatty acid composition of human RBCs to assess degrees of malabsorption in clinical disorders or adherence to a prescribed dietary regimen. However, our study[45] showed that although the fatty acid composition of RBC phospholipids of infants with EFA deficiency and at recovery follow a pattern similar to that of plasma, these changes occurred more slowly. Increased RBC osmotic fragility was reported in EFA-deficient rats.[57] However, we[45] did not demonstrate changes in RBC osmotic fragility in neonates with rapid onset of EFA deficiency.

Effect on Platelets.—Recently, the importance of arachidonic acid biotransformation in platelets has been elucidated.[51] In addition, hemorrhagic problems of unknown etiology are common in sick low-birth-weight infants.[58] Many premature infants are being given TPN, and EFA deficiency is a frequent occurrence.

Hence, we examined the rapid onset of EFA deficiency in premature infants and its possible effect on platelet function. We found[59] that the EFA-deficient infants had impaired platelet aggregation when compared with controls (Fig 6). In addition, the platelets from EFA-deficient infants demonstrated evidence of disaggregation. On recovery from their deficient state, the low-birth-weight infants had platelet functions similar to those of apparently healthy premature infants.

The relationship between the platelet dysfunction and EFA deficiency is not clear from this study. However, it is attractive to speculate on the possible connection between arachidonic acid depletion (ie, EFA deficiency) and platelet dysfunction. Thromboxane A_2, a key mediator of human platelet aggregation,[60] is formed from arachidonic acid, and the blockage of its synthesis results in abnormal platelet aggregation.[60] Decreased prostaglandin formation in vivo has been noted in EFA-deficient infants[61] and in vitro in tissues of EFA-deficient animals.[62] But in vitro platelet studies in EFA-deficient animals have shown conflicting results, perhaps because of the species differences or other possible defects that are known to be factors in platelet behavior and may contribute to hemorrhagic disorders.[63] Normal platelet phospholipid is important in the aggregation phenomenon and arachidonic acid is an important component of membrane phospholipids.[64] The EFA deficiency state may reduce the availability of arachidonic acid to the platelet.

Finally, it is not known whether or not the abnormality of platelet aggregation in those EFA-deficient patients truly reflects the plasma abnormality since the accumulation of Δ-5,8,11-eicosatrienoic acid itself depresses platelet aggregation.[65] This fatty acid is found in important amounts only in subjects with EFA deficiency. It is also not clear whether EFA deficiency leads to increased permeability and fragility of blood vessels.[66]

Effect on Prostaglandins.—Van Dorp[62] studied the prostaglandin content of various parts of the kidney medulla, in normal and EFA-deficient rabbits. These studies demonstrated that EFA deficiency in rabbits is associated with prostaglandin deficiency. It was suspected, but not proved, that in the EFA-deficient animal, there is a sharp decrease in precursor acids.[62] This hypothesis is supported by Kaa,[67] who showed increased activity of prostaglandin synthetase in vitro in EFA-deficient rats.

We[61] measured the excretion of the major urinary metabolite of prostaglandins E_1 and E_2, 7α-hydroxy-5,11-diketotetranorprostane-1,16 dioic acid (PGE-M) for three infants during EFA deficiency and at recovery from the deficiency state and for nine thriving control neonates. A significant difference between the PGE-M excretion in the group of infants with EFA deficiency before and after treatment was found ($P < .05$) (Fig 7). Significant differences ($P < .05$) in PGE-M excretion were also found between the control and EFA-deficient infants.

The biochemical evidence of EFA deficiency and the decreased levels of PGE-M excretion are rapidly corrected when patients resume a diet containing EFA. Since PGE-M is the terminal product arising from sequential 15-dehydrogenation, Δ 13 reduction and both β and ω oxidation of prostaglandins E_1 and E_2, any decrease in its excretion reflects decreased prostaglandin synthesis and turnover in the body.[68] This decrease is probably related to a decrease in the precursor EFA, although synthetase deficiency or altered prostaglandin metabolism has not been excluded. The observation that feeding arachi-

donate to humans increased the excretion of PGE-M[69] indicates that the excretion of this prostaglandin metabolite is related to the amount of arachidonic acid in the precursor lipids. Because prostaglandins and thromboxanes are not stored in tissues, PGE-M excretion usually indicates biosynthetic activity for which both prostaglandin synthetase and substrate must be present.

Effect on Pulmonary Surfactant.—Deficiency in EFA has been shown to cause a respiratory disease syndrome in chickens,[47] and in rats it resulted in a substantial reduction in palmitate content of lung surfactant.[70] Lung structure is not altered by EFA deficiency except for mitochondrial changes confined to type II cells,[52] and the alteration in lung mechanics in EFA-deficient rats resulted from impaired surfactant surface-tension-lowering activity.

Fig 5.—Infant with skin lesions during essential fatty acid deficiency (from Friedman et al[45]).

We[71] studied a low-birth-weight infant who had biochemical evidence of EFA deficiency in the plasma after suffering from chronic bronchopulmonary dysplasia and recurrent episodes of necrotizing enterocolitis. A lower than normal level of palmitic acid and an increased level of palmitoleic and oleic acids were seen in pulmonary surfactant phospholipid components. On treatment and recovery from EFA deficiency, the fatty acid pattern both in plasma and surfactant phospholipids returned to normal, along with clinical improvement in the respiratory illness. The major molecular species of phosphatidylcholine in lung tissue and lavage fluid is dipalmitoyl phosphatidylcholine.

Phosphatidylcholine is considered to play an important role in determining the surface properties of pulmonary surfactant. Reduction of this species of phosphatidylcholine results in surfactant with diminished surface-tension-lowering capacity in EFA-deficient rats.[72]

Besides phosphatidylcholine, the surfactant complex contains other highly characteristic phospholipid components. In the adult, the second major phospholipid is phosphatidylglycerol, but it has not been demonstrated in infants with hyaline membrane disease. The association between EFA deficiency and the impairment of surfactant phosphatidylcholine and phosphatidylglycerol fatty acid composition has been shown in our patient. This alteration may diminish lung function and so contribute to the pathophysiology of hyaline membrane disease, chronic bronchopulmonary dysplasia, cystic fibrosis,[73,74] and other respiratory diseases associated with inadequate nutrition, inviting an EFA deficiency.

Effect on the CNS and Retina.—The availability of long-chain PUFAs seems to be related to the degree of brain and CNS development. Linoleic and α-linolenic acids represent a small proportion of the fatty acyl components of the phosphoglycerides of fetal brain.[24] In contrast, arachidonic and docosahexaenoic acids, more unsaturated EFAs, are readily incorporated into the structural lipids of the developing brain.[24] In man, the brain undergoes an accelerated growth

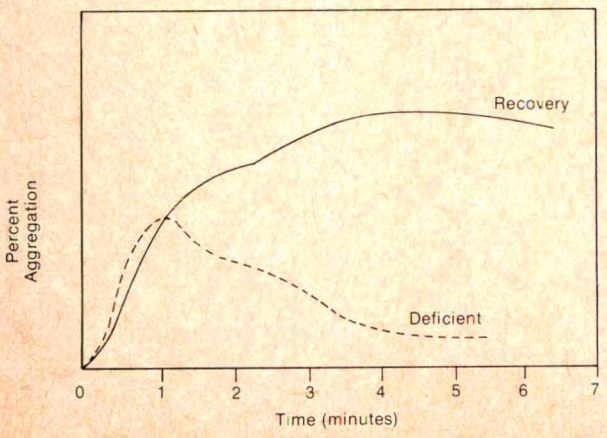

Fig 6.—Platelet aggregation patterns at 5.0 μM adenosine 5′-diphosphate during deficient period and ten days after feeding (recovery period).

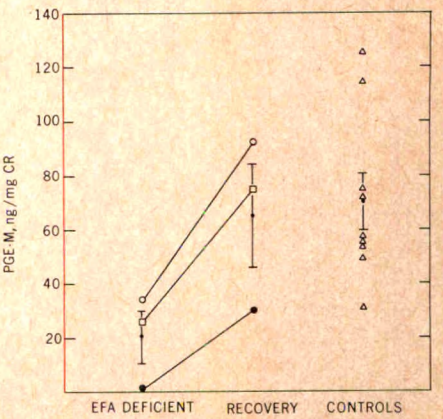

Fig 7.—Comparison of urinary excretion of 7α-hydroxy-5,11-diketotetranorprostane-1,16 dioic acid (PGE-M), expressed as ng/mg urinary creatinine (CR), for infants with essential fatty acid (EFA) deficiency and at recovery and for thriving neonates. Values expressed as mean ± SEM (from Friedman et al[61]).

phase during the last trimester of pregnancy and the first 18 months of postnatal life. During this vulnerable period, EFAs are required for structural expansion of the brain.

The effect of EFA-deficient diet during gestation, lactation, and postnatal development has been studied in the rat. Paoletti and Galli[75] reported that during fat-free diet, brain weight is decreased; total lipid and phospholipid concentrations are diminished; and the fatty acid composition of phospholipids, especially ethanolamine phosphoglyceride (which is the major highly unsaturated phospholipid constituent of brain membranes), is considerably modified. This EFA-deficient diet induces changes that involve decrease in the $\omega 6$ and $\omega 3$ fatty acids and increase in the $\omega 9$ acids. The EFA-deficient rats showed an impaired performance compared with the control, EFA-supplemented group. During the period of growth when they were returned to the control diet, the EFA-deficient rats were able to recover completely, but a permanent learning disability remained.

White et al[76] studied the brain lipids of three premature infants whose conditions were maintained by fat-free parenteral nutrition and who died. They demonstrated fatty acid alterations indicative of EFA deficiency in the two major component phospholipids of the brain, ethanolamine and choline phosphoglycerides, in the cerebrum and less so in the cerebellum. There was also a tendency toward reduction of brain phospholipid concentration in these infants.

The phospholipid composition of the retinal cells is similar to the rest of the brain. Evidence was presented[77] to show that the rate of renewal of photoreceptor membranes is dependent on the availability of dietary EFAs, and the electrical response of the photoreceptor cell membranes seems to be a function of the position of the double bond as well as a function of the total number of double bonds in fatty acid supplements.

PUFA REQUIREMENTS

The earliest estimate of the infant's requirement for linoleic acid as approximately 1% of the calories was based on clinical observations, caloric intake, and serum levels of the dienoic, trienoic, and tetraenoic acids.[40] When the means of assessing the linoleate requirement from a curve relating the triene-tetraene ratio to intake of linoleate was developed,[1] it became apparent that the requirement of infants could be deduced from this biochemical parameter as well. Extensive data relating PUFAs of human serum to intake of linoleate are presented in the classical study of Hansen et al.[17] From that study, it seems that 1% of calories is a minimum requirement and that 4% of calories is an optimal intake. The plot of the triene-tetraene ratio of serum fatty acids vs linoleate intake of infants shows that the low ratio indicative of normal EFA metabolism was reached by about 1% of calories from linoleic acid.[7] The effect of variable dosage of dietary intake of linoleic acid on the total dienes, trienes, and tetraenes of serum indicated that 1% to 2% of calories as linoleate satisfies the requirements for all the biochemical conversions of PUFA, as well as permitting normal growth and preventing dermatitis.

The potency of arachidonic acid as EFA has been shown to be greater than that of linoleic or γ-linolenic acids, but all are effective in the treatment of EFA deficiency and promote normal growth. Although the α-linolenic acid ($\omega 3$) series has been considered to be essential, it cannot fulfill all the functions of the $\omega 6$ series, and so it has been questioned as possessing true essentiality. Although tissues, the CNS tissues in particular, contain a relatively high proportion of the metabolic products of α-linolenic acids, we must await demonstration of their particular function.

SUPPLEMENTATION OF PUFA

Traditionally, linoleic acid is considered the dietary EFA, for it is the commonest fatty acid that will provide all the requirements known for PUFAs in humans and animals, and it can function alone in the diet to meet the EFA requirements.

Diets

Human Breast Milk.—The fatty acid composition of human milk has been studied in detail. The patterns of fatty acids from the two breasts were found to be similar after the same nursing, but fasting and time of day both influenced total fat and fatty acid composition of the milk.[78] Fatty acid composition of breast milk changes with the nature of the dietary fat.[79] With the trend in the American diet toward a higher proportion of unsaturated fatty acids including linoleate, there is an increase in breast milk linoleate content that can vary from 1.0% to 43.0% of total fat. However, an average content ranges from 8% to 10%. Since fat provides about 50% of the calories in human milk, it contains more than an adequate amount of the EFA linoleate.

Infant Formulas.—The American Academy of Pediatrics[80] has recently recommended that infant formulas should contain a minimum of 3.3 g of fat per 100 kcal (30% of calories) and 300 mg of linoleic acid per 100 kcal (approximately 2.7% of total calories) to provide a fat-carbohydrate ratio within a range that is customary in infant diets. The Academy was concerned that excess linoleic acid would produce peroxidation and increase the vitamin E requirement, but it did not set an upper limit on the linoleate content of the diet, noting that in some human milks the linoleic acid content is 8% to 10% of the fat. However, previous reports[79] demonstrated that the linoleic acid content in breast milk varies widely with the mother's diet.

Several of the most widely used formulas in the United States are based on cow's milk protein with added lactose. All contain vegetable oils of one type or another. The fatty acid composition and fat content of infant formulas are summarized in the Table. All the formulas contain considerably more linoleic acid than human milk lipids. The long-term effects of these dietary regimens are unknown.

Parenteral Fat Emulsion.—In the newborn infants, it is difficult to provide an optimal caloric intake in the form of amino acids and carbohydrates because excessive fluid volumes are needed when isotonic solu-

tions are used, and the glucose load provided by hypertonic solutions is frequently not tolerated. Therefore, soybean oil emulsion (Intralipid), which has a high caloric density and low osmolality, has been used increasingly to provide additional calories and EFAs.[81,82] This emulsion, like most vegetable oils, is rich in the EFA linoleate, which accounts for 54% of its fatty acid content. Several studies[81,82] documented the efficacy of the administration of Intralipid in alleviating clinical and biochemical manifestations of EFA deficiency.

Inunction of Oil.—Inunction of EFAs was found to relieve EFA deficiency in animals.[83] Cutaneous application of esters of linoleic or arachidonic acids or sunflower seed oil, a rich source of linoleic acid, reduced the elevated rate of transepidermal water loss in deficient rats,[83] whereas topically applied dinoprostone (prostaglandin E_2) effectively cured the scaly skin of EFA-deficient rats.[84] Inunction of sunflower seed oil to the forearms of patients with EFA deficiency lowered the rate of water loss, cured scaly lesions, and corrected the abnormal skin lipids[85] and restored their plasma fatty acid patterns to normal, indicating that penetration of the linoleic acid through the skin had occurred.

We[45] studied two sick newborn infants who received fat-free parenteral nutrition and had biochemical and clinical evidence of EFA deficiency. After the inunction of sunflower seed oil, these manifestations disappeared. However, it seems impossible from our studies to predict the exact amount of the absorption of linoleic acid after inunction. Even the cutaneous application of relatively large quantities used with our patients failed to replenish tissues deficient in EFA.

We recently demonstrated the ability to correct platelet dysfunction and to increase prostaglandin E biosynthesis and turnover by the inunction of sunflower seed oil to newborn infants with EFA deficiency.[61] The failure to demonstrate biochemical correction of EFA deficiency in the serum of certain infants[86] is not entirely surprising since during fat-free parenteral alimentation, the outflow of linoleic acid from adipose tissue is blocked at least in part by the high blood insulin levels accompanying dextrose administration.

Plasma.—It has been recommended[87] that the prevention and/or treatment of EFA deficiency may be provided by biweekly infusion of plasma, 10 mL/kg. However, a 1.0-kg infant requires 1 calorie of linoleic acid for each 100 calories. Fasting adult plasma has approximately 1 mg/mL of linoleic acid; thus, for each 100-calorie total intake, the infant requires about 110 mL of plasma to supply adequate linoleic acid. This would be impractical. We[29] have shown that neither two exchange transfusions performed on two sick infants on different days during the first week of life nor repeated blood transfusions could prevent or correct the rapid onset of EFA deficiency.

EXCESSIVE PUFA INTAKE

Since Burr and Burr[2] demonstrated the importance of certain fats necessary for normal growth, research on EFAs has been mainly concerned with the symptoms of EFA deficiency and the administration of the minimal EFA requirement to prevent or treat the deficiency state. However, little is known about the toxicity or adverse effects of high levels of these substances in the diet.

Toxic Effects of PUFAs

Several hazardous effects of Intralipid have been reported for the newborn infant: (1) a reduced plasma clearance rate in small-for-date infants, as well as among premature infants born before 32 weeks of gestation and during an acute illness[81,88]; (2) displacement of bilirubin from albumin binding sites and an increased risk of kernicterus in the jaundiced newborn; (3) the deposition of lipid material in macrophages that may alter immunity[89]; (4) immunosuppressive effects[90]; (5) and the potential risk of substitution of phytosterols for cholesterol in the developing CNS, which

could lead to changes in myelin configuration and function.

We[82] studied two sick low-birth-weight infants who received TPN, including soy bean oil emulsion for the first 9 and 12 weeks of life, respectively. There was an increase in the total concentration of the plasma triglycerides and free fatty acids when these values were compared with control infants receiving infant formulas. Histological examination of the lung (Fig 8), after the administration of Intralipid, indicated numerous globules of sudanophilic material in alveolar macrophages and capillaries. Thus, it is possible that prolonged administration of this infusion may be associated with altered pulmonary gas exchange[91] and reticuloendothelial system function.

Effect on Tissue Fatty Acid Composition and Prostaglandin Biosynthesis

We[92] have measured tissue lipid composition and the excretion of PGE-M in three infants who received TPN including this soy bean oil emulsion for several weeks, and we have compared these values with control infants. Linoleic acid was incorporated into the major lipid classes of the plasma, RBCs, and tissues in the infants receiving Intralipid. Concomitant with the increase in the relative concentration of linoleate, a decrease in the higher PUFA arachidonate was apparent. This may indicate a competition for storage in tissue lipids, a balanced content of the intake of the linoleic and linolenic acids, a rapid turnover of the long-chain PUFAs, or a combination of these factors. However, the sum of the two EFAs, linoleate and arachidonate, is similar in RBCs and tissue phospholipids of control infants and those who received Intralipid.

A significant difference ($P < .05$) between the PGE-M excretion for the group of infants before and after the administration of Intralipid was found in this study. Differences in the urinary excretions were seen between the control group and the infants receiving soy bean oil emulsion. The PGE-M excretion after the administration of Intralipid was similar to that obtained from infants with EFA deficiency. The decrease in PGE-M excretion in patients receiving a high content of linoleic acid is most likely related to a decrease in the precursor EFA, arachidonate, although an inhibiting effect of linoleic acid on prostaglandin synthesis is possible.[93]

Effect on Platelet Function

Long-term administration of a diet rich in linoleate reduced the platelet aggregation in laboratory animals and man.[94] We (unpublished data, October 1978) observed that prolonged administration of Intralipid to sick newborn infants resulted in changes of the fatty acid composition of their platelets and phospholipids, and those platelets showed reduced aggregation in response to different agents known to induce platelet aggregation.

Effect on Cholesterol

Dietary cholesterol and the ratio of PUFAs to saturated fatty acids are important determinants of the plasma cholesterol concentration, and modification of these two factors may reverse hypercholesterolemia. However, studies on the effect of dietary cholesterol and PUFAs on the plasma cholesterol in infants have yielded conflicting results.[95,96] Infants fed commercial formula rich in vegetable oil failed to show differences in serum cholesterol values when compared with infants fed human or cow's milk by the age of 2 years,[97] although slightly lower cholesterol level was detected by the age of 7 to 12 years.[98] Increased consumption of PUFAs by nursing mothers resulted in an increase in the linoleic acid level in their milk and in the infants' serum, and although the cholesterol content remained unchanged in the milk, it declined in the infants' plasma.[99]

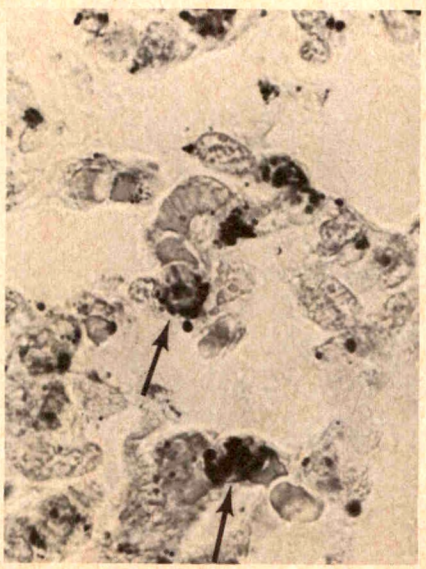

Fig 8.—Photomicrograph of lung, showing diffuse deposition of fat globules in alveolar macrophages and capillaries after administration of soy bean oil emulsion (Intralipid) (arrows) (oil red O, original magnification ×1,280) (from Friedman et al[82]).

RELATIONSHIP OF DIETARY PUFA TO VITAMINS

Vitamin E

Vitamin E seems to function primarily as an antioxidant, preventing peroxidation of membrane lipids, and as such, it contributes to the stability of the lipid structures in biological membranes. Plasma vitamin E concentration of the newborn infant is about one third that of adults, and that of the low-birth-weight infant is even lower.

A number of factors make the low-birth-weight infants more susceptible to vitamin E deficiency. These infants are born with meager stores of vitamin E and relatively small fat deposits in which the vitamin is normally stored. The capacity of the low-birth-weight infants to absorb fat and fat-soluble vitamins is limited in comparison with the full-term infant. These infants are usually fed proprietary milks in which the fat is supplied in the form of vegetable oil rich in PUFAs, particularly linoleate. It has been shown that the dietary requirement for vitamin E increases with increasing amounts of dietary PUFAs.

Although most vegetable oils with a high linoleic acid content are considered a natural source of vitamin E, it was found that vegetable oils contain a considerable amount of γ-tocopherol[100] that has only about 10% of the biological activity of α-tocopherol. Although the amounts of vitamin E usually found in formulas may be adequate to maintain normal serum tocopherol levels in term infants, these

may not be sufficient for premature infants. Thus, a relative vitamin E deficiency state may occur in these infants. In addition, these high-PUFA diets are supplemented with iron, which increase the vitamin E requirement in these low-birth-weight infants.[101]

The Committee on Nutrition of the American Academy of Pediatrics[102] recommends that the full-term infant receive 0.3 IU of vitamin E per 100 kcal and at least 0.7 IU of vitamin E per gram of linoleic acid, and it recommends that formula fed to premature infants should provide 0.7 IU of vitamin E per 100 kcal and at least 1.0 IU of vitamin E per gram of linoleic acid. In addition, the Committee recommends that the multivitamins supplement given to low-birth-weight infants should provide 5 IU of vitamin E, preferably in water-soluble form.

Pyridoxine Hydrochloride (Vitamin B_6)

The role of pyridoxine in fat metabolism and in the metabolic conversions of the EFA has been demonstrated in man and animals.[103]

PUFA INVOLVEMENT IN DISEASE STATES

Abetalipoproteinemia

The primary defect in abetalipoproteinemia is failure of synthesis of apo B, which is the major apoprotein of betalipoprotein and is also essential for the formation of prebetalipoprotein and chylomicrons.[104] The disorder usually occurs in infancy, with symptoms owing to malabsorption of fat; later, retinal and neurological abnormalities occur. Analysis of PUFAs in the plasma and RBC of these patients showed linoleic acid to be depressed and $\omega 9$ acids elevated, a patter consistent with EFA deficiency; however, a normal triene-tetraene ratio make the diagnosis of EFA deficiency state unlikely. The low level of linoleic acid may contribute to the abnormal neurological function but is unlikely to be the sole cause. Vitamin E deficiency in this condition could contribute to the deleterious effect of altered EFA metabolism on the stability and integrity of cell membrane.

Acrodermatitis Enteropathica

Acrodermatitis enteropathica is a rare disorder of infancy characterized by cessation of growth, distinct epidermal lesions, malabsorption, alopecia, dystrophy of the nails, and psychic disturbances. Aberration in the metabolism of PUFAs is considered as a factor in the pathogenesis of the disease. During exacerbations, the level of arachidonic acid in serum lipids is low, whereas linoleic acid content is higher than normal and a number of unusual unsaturated or branched fatty acids accumulate. Response to the administration of zinc chloride, diiodohydroxyquin (Diodoquin), and also parenteral fat emulsions have been reported.

Familial Deficiency of Plasma Lecithin: Cholesterol Acyltransferase

This rare disorder involves a deficiency of an enzyme that normally occurs in the plasma and transfers acyl groups, principally linoleic and arachidonic acids, from the β position of lecithin to form cholesterol ester. The principal effects include low plasma cholesteryl ester, decreased lysolecithin, deficiency in α-lipoprotein in the plasma, proteinuria, anemia, and corneal opacity. As a result of the deficient eyzyme, the plasma cholesterol ester concentration is low; and of these cholesteryl esters, the esters of saturated acids and oleic are relatively high in concentration, whereas those of linoleic and arachidonic acids are reduced. Transfusion of normal plasma containing the enzyme corrects the biochemical abnormalities.

Cystic Fibrosis

Abnormal fatty acid composition of various tissues and blood-lipid fractions has been described in patients with this disease and is characterized by a low level of linoleic acid and usually a concomitant elevation of palmitic, palmitoleic, and oleic acids.[75,105,106] The clinical course of cystic fibrosis is favorably influenced by regular IV infusions of oil emulsions rich in linoleate.[107] On the basis of these findings, it has been suggested that a defect in fatty acid metabolism in cystic fibrosis might contribute to the clinical manifestation of this disorder.[73] However, when fatty acid composition of the various plasma-lipid fractions from patients with cystic fibrosis with and without pancreatic insufficiency, from obligate heterozygous subjects, and from normal subjects was determined, only the patients with cystic fibrosis with pancreatic insufficiency had substantially abnormal fatty acid composition.[106] Vitamin E deficiency and possible altered prostaglandin biosynthesis[107] may contribute to the pathophysiology of cystic fibrosis.

Essay

Hyperactivity

Symptom Complex or Complex Symptom?

Melvin D. Levine, MD, Frank Oberklaid, MBBS, FRACP, DCH

• The phenomenon of "hyperactivity" is well recognized. Results of long-term follow-up studies show that children diagnosed as "hyperactive" are at risk for severe problems during adolescence and adulthood. However, no common diagnostic criteria exist for "hyperactivity." The term can refer to a number of very different behaviors, and children diagnosed as "hyperactive" may also exhibit one or more concomitant difficulties. A "hyperactive" child should be carefully assessed to determine the nature of the behavioral problem and its source, and the term "hyperactivity" itself should be used with caution.

(*Am J Dis Child* 134:409-414, 1980)

Professionals from a multitude of disciplines continue to be perplexed about the enigma called "hyperactivity." Its clinical phenomenology is well recognized: there exist a group of children who have trouble directing their attention and activity. They are likely to encounter difficulty in the classroom, on the playground, in the neighborhood, and at home. Often they exasperate themselves, their siblings, their peers, and the adults in their lives. Although the clinical picture is familiar, some fundamental questions remain. Is there a genuine homogeneity to this group? Does the clinical picture in fact describe a syndrome? Does there exist commonality with regard to etiology, pathogenesis, prognosis, and management? What becomes of these children as adults? Are there predictable consequences and sequelae of growing up hyperactive?

LONG-TERM FOLLOW-UP

An article published in the *Archives of General Psychiatry*[1] reported a prospective study of 75 hyperactive children who were followed up for ten years. They were seen initially in the Psychiatry Clinic at the Montreal Children's Hospital between the ages of 6 and 12 years. Some had received medications as part of their management (including chlorpromazine and/or amphetamines, but no methylphenidate hydrochloride). The patients as young adults were reevaluated, with a full psychiatric assessment and a review of historical data. They were compared with a control group. The former had a higher prevalence of certain traits, including impulsivity and "immature dependency." There were several common biographical characteristics: (1) The hyperactive group had had more changes of residence, had had fewer years of education than controls, and had received lower grades in high school. (2) The hyperactive group had a higher school dropout and expulsion rate. (3) More hyperactive than control subjects had been seen in court. (4) There was also a much higher percent of hyperactive subjects who had been using nonmedical drugs during the year prior to follow-up. An important finding was a higher occurrence of automobile accidents among the hyperactive subjects.

This study by Weiss et al[1] is consistent with several previous retrospective and follow-up reports, which suggest that those youngsters who are identified as "hyperactive" are at risk for a wide range of problematic adolescent and adult outcomes.[2,3] It is noteworthy that these sequelae impinge on areas beyond those linked to formal classroom preparation. Automobile accidents, difficulty with the law, drug and alcohol abuse, and other forms of life instability may be common phenomena.[4] This has significant implications for pediatrics; for at times there is a tendency to relegate school dysfunction to the educational sector, which suggests that they are purely learning problems. The growing body of evidence of a broad impact

of such dysfunctions in later life suggests that appropriate diagnosis and management is a critical part of preventive pediatrics.[5]

SAMPLE SELECTION CRITERIA

In conducting their prospective study, Weiss et al made an assumption that commonly haunts most investigations of "hyperactivity," namely, that they were studying a more or less discrete clinical entity. They used five selection criteria for "hyperactivity":

(1) Restlessness and poor concentration were their main complaints, and had been present since the earliest years. (2) The complaints were a major source of problems both at home and at school. (3) All children had IQs above 85. (4) None of the children were psychotic, borderline psychotic, epileptic, or had cerebral palsy. (5) All children were living at home with at least one parent.

It seems that the major selection criteria concerned chronic restlessness and poor concentration both at home and in schoool.

Other studies of "hyperactivity" have emphasized different traits (Table 1). There exists no clinical or investigative consensus. Therefore, it is possible, and in fact likely, that various investigators may be scrutinizing populations of children who are called "hyperactive," but who are in fact very different from each other.[5,19-22] Research of such youngsters in a learning disabilities clinic may involve a population that differs from a sample drawn from a psychiatry clinic, a public school, or a private pediatric practice.[22,23]

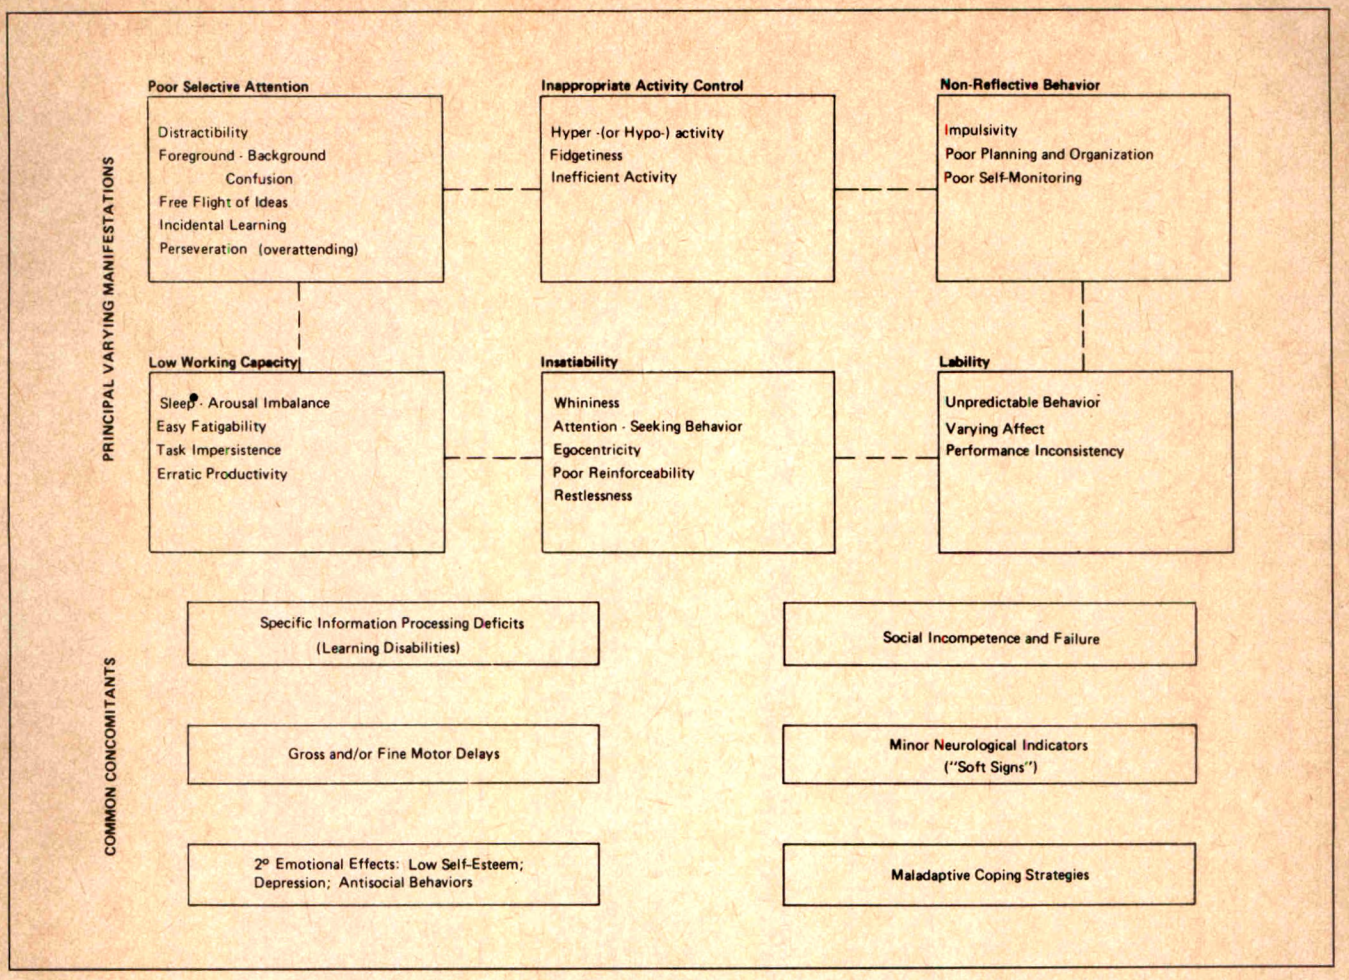
INDIVIDUAL TRAITS

The Figure depicts six basic categories of symptomatology that have been commonly reported in children said to be "hyperactive." Not all youngsters who are suspected of "hyperactivity" manifest all of these symptoms. Within a population of such patients, there is likely to be considerable heterogeneity with regard to the "penetrance" of individual traits. Moreover, any one symptom in itself suggests a differential diagnosis that goes beyond "hyperactivity" on a neurological or constitutional basis. For example, many of these symptoms also can be manifestations of childhood depression or of anxiety[24]; others may be acquired behaviors induced by the social or family milieu. Some children are impulsive during cognitive tasks because of problems with short-term memory; they need to perform before they forget what they were setting out to do. A child can become chronically inattentive because of a specific information-processing problem.[25] Thus, a youngster with a receptive language disability may become secondarily fidgety, easily distracted, and poorly focused.

Some of the traits summarized in the Figure may have existed from the

Table 1.—Admission Criteria Used in Recent Studies of Hyperactivity

Study	Symptoms Emphasized	Other Diagnostic Criteria
Bugental et al[6]	Group 1: "Behavior or attention problems"; already receiving methylphenidate Group 2: Rated high on hyperactivity dimension of Conners' Teacher Rating Scale[7]	Group 1: No information given about diagnostic criteria Group 2: No data for scores on Teacher Rating Scale; 4 of 32 children had severe learning problems
Coleman[8]	Increased activity, low frustration tolerance, impulsivity, short attention span with easy distractibility, difficulty in large groups	No information regarding specific admission criteria or sources of data for described behaviors; no school data
Conners et al[9]	Severe overactivity, short attention span, distractibility, poor frustration tolerance, disruptive behavior, failure to progress at school at rate expected on basis of potential	Intelligence quotient ≥ 80; also to have one or more of 7 listed indicators of minimal brain dysfunction, parent and teacher report, clinical evaluation
Greenberg et al[10]	Hyperactivity, impulsivity, poor attention span, poor academic performance	Diagnosis already made by referral agencies and confirmed by authors; criteria not mentioned
Greenhill et al[11]	Hyperactivity, aggressiveness, poor attention span, neurological soft-signs, antisocial behavior	Parent report and Conners' Parent Questionnaire;[12] no school data
Harvey and Marsh[13]	"Well above average" levels of activity, short attention span in learning tasks, distractibility, lack of impulse control, impaired social relationships	Normal intelligence; no school data; criteria not mentioned
Rapoport et al[14]	Persistent distractibility or motor restlessness and impulsivity	Diagnosis made by referral sources; no school data. Intelligence quotient ≥ 80; middle class
Satterfield et al[15]	Hyperactivity and distractibility plus at least 6 of 28 symptoms "found to be characteristic of the syndrome"	Criteria of Stewart et al[16] males only Intelligence quotient ≥ 80; no school data
Schain and Reynard[17]	Short attention span, restlessness, distractibility, impulsivity	Symptoms noted by referral sources; criteria not mentioned; no school data
Stewart et al[18]	Overactivity, short attention span	Symptoms described by mother; no school data



Individual traits that have been described in children with "hyperactivity."

earliest weeks of life.[26,27] In other instances, however, such manifestations may await the provocative rigors of school.[17,28] In addition, the symptoms may be situation-specific and not be evident in every setting.[29]

Many authors have believed that poor selective attention is the most pervasive common denominator in the population.[30-33] The American Psychiatric Association lists a diagnosis of Primary Attentional Disorder.[34] Problems with selective attention are likely to find expression in high levels of distractibility,[35] confusion over foreground and background (either visual or auditory, or both),[36] a tendency toward the free flight of ideas (ie, free association and daydreaming), and a propensity for incidental learning.[23] The latter involves the indiscriminate absorption of a great deal of irrelevant information, without learning in a focused manner at the right time and in the right place.

The term "hyperactivity" suggests increased motor output. Recently, however, there has been a growing awareness of "hypoactive-hyperactive" children.[34] These youngsters are distractible, impulsive, poorly organized, yet underactive. Paradoxically, some children with "hyperactivity" may exhibit appropriate *quantities* of activity.[38] What is clear is that we need to consider the *quality*, or goal-directedness, of activity rather than its overall amount.[28,39] Many of these children are not energy efficient. Their activity is misdirected, purposeless, fidgety, and seemingly random. This is an important distinction, since there exist youngsters who are restless and overactive, but purposeful and selective.[40] Such efficient children should not be confused with "hyperactive" youngsters.

It has been reported that children with "hyperactivity" seldom are reflective.[28,30,31,41] They tend to be chronically impulsive.[32] This may be seen in their overall behavior, in their social interactions, and in their efforts at problem solving. They tend not to reflect, plan, organize, or monitor their own productions. Many such youngsters feel very much out of control. Their impulsivity is constantly getting them into trouble. Often they seem not to believe what they have done, feeling unaccountable for their unpremeditated acts because things seem to happen so fast.

Many of these children seem incapable of sustained work effort. They fatigue easily doing cognitive tasks and have difficulty sustaining attention.[42] They may have problems in enduring requisite delays of gratification to achieve work.[43] They may be impersistent and inconsistent, and show fluctuating levels of arousal and

alertness. Some authors have suggested that these children are "underaroused,"[44] that they are engaged in a constant struggle to thwart fatigue. They may have as much difficulty sleeping at night[5,43] as they have in remaining alert during the day. In such cases, stimulant medication may serve to enhance arousal, alertness, and ultimately productivity.

Insatiability is a trait that has been associated with poor selective attention. Children so affected seem to be chronically restless, need to be the center of attention, often are whiny and dissatisfied, and act excessively egocentric.[32] They may respond poorly to either positive or negative reinforcement, and are therefore relatively insensitive to punishment. The value of rewards is likely to be transitory, seeming only to whet the child's appetite and heighten the intensity of need.[29]

Children said to have "hyperactivity" are described as "emotionally labile."[39] Accompanying their substantial array of inconsistent behaviors is a tendency toward capriciousness of mood or affect. Their behavior may vary from moment to moment, their personalities seeming to change with little provocation or justification. Wide mood swings are common and difficult to account for.[43]

COMMON CONCOMITANTS

Complicating the clinical scenarios is the recognition that these heterogeneous manifestations are accompanied by equally varied concomitant disabilities. Many (but by no means all) children with symptoms of hyperactivity also have learning disabilities.[18,45] These may range from problems with visual-spatial orientation, to difficulties with the processing of sequentially presented information, to specific language disabilities. Often the information-processing problem in itself is a disorganizing influence, impairing attention, precipitating impulsive behavior, and contributing to the child's poor self-esteem. Some youngsters said to be hyperactive also manifest significant delays in gross and/or fine motor function and visual motor integration.[9,31,45,46] Again, such associations are by no means invariable.

Social failure is another common concomitant. Many such children have difficulty forming, sustaining, and understanding peer relationships.[47,48] Their impulsivity may be threatening to other children. They may be imperceptive socially, unable to interpret or act on visual and verbal cues from others, and lack a social feedback response system. They may have difficulty predicting the social consequences of their acts. Ultimately they may experience increased social alienation, peer rejection, and stigmatization, all of which can intensify their anxiety, alter affect, and diminish self-esteem.[49]

There is some evidence that children with problems of attention and activity exhibit minor neurological signs (sometimes called "soft signs"), including associated movements, dysdiadochokinetic movements, and other indicators of neuromaturational delay.[50,51] It may well be that one subset of children with problems of attention and activity actually manifest a delay in the maturation of the CNS.[52]

It is not surprising that children who endure academic failure, adult disapproval, peer rejection, and loss of control are likely to acquire secondary emotional problems.[53] Depression, psychosomatic symptoms, and sociopathic behavior may ensue. These may be the end products of chronic frustration, of mismatching to adult expectancies, and of long-standing failure. Nor is it surprising that, out of desperation, some youngsters appropriate maladaptive strategies to deal with their failures and to save face. Aggressive behavior, class clowning, social withdrawal, or blatant defiance of adult expectations may be examples of such defensive maneuvers. Sometimes these symptoms may be inappropriately attributed to primary emotional disturbances.

PHYSIOLOGICAL CORRELATES

Most studies have used behavioral criteria to select subjects and document outcomes. Among these have been investigations of physiological and biochemical parameters in this group of children. Several investigators have concluded that some of these youngsters have aberrations in their CNS metabolism of biogenic amines.[54,55] Others have investigated various electrophysiological parameters, including EEG findings, evoked cortical potentials, and autonomic nervous system responses, in an attempt to define common pathophysiological mechanisms or to preselect those children who will respond to medication.[56]

ACKNOWLEDGING HETEROGENEITY

In view of the heterogeneity of this group of children, it is unlikely that there will emerge a unitary biochemical or physiological explanation for "hyperactivity." Nevertheless, further studies may allow us to define subgroups of these children with biochemical or physiological criteria. Meanwhile, given the multitude of constellations and severities of manifestations in this population, the process of sample selection for a research project is hazardous.[5] It is imperative that future investigation offer more detail in the description of the population studied, because the natural history and treatment of a child who has attention problems and a language disability may be quite different from those of a child whose dysfunction is accompanied by no information-processing problems whatsoever. Likewise, those youngsters whose major manifestation is impulsivity may have a different prognosis and pathophysiology from those whose problems exist mainly in the areas of selective attention and work output. Lumping all such youngsters together to describe a natural history is likely to result in a growing mass of nonreplicable research.[17]

Recently there has been considerable interest in the term *attention deficit disorder*. This too may turn out to be an overly inclusive categorization. We have suggested one approach toward the differentiation among children thought to have attention problems.[25,29] This is given in Table 2. Some children seem to have a *primary attention deficit*. They are thought, on

Table 2.—Attention Deficits and Their Differentiation
Primary attention deficit Constitutional neurological weakness of selective attention Variable clinical manifestations (see Figure) Present through most of child's life Pervasive in multiple settings
Secondary attention deficit Inattention as a response to one or more deficits in information processing (ie, learning disabilities) Outward symptoms similar to primary attention deficit May not be manifest until vulnerable areas of learning are challenged or Inattention as a result of emotional preoccupations (ie, chronic "drainage" of attention), losses, or psychosocial problems Outward symptoms similar to primary attention deficit
Situational inattention Inattention precipitated by "mismatching" of child with settings and/or expectations Likely to be present exclusively or primarily in specific places or circumstances
Mixed forms Combinations of other forms relative importance of components may evolve with age

a clinical basis, to have relatively "pure" problems with selective attention, a primary constitutional disorder in the CNS "circuits"; yet it must be emphasized that, even within this group, there is considerable symptomatic heterogeneity. For example, some such children may have predominant impulsivity, others sleep-arousal problems, whereas others primarily have a high level of distractibility.

Another subgroup have *secondary attention deficits*. These children are likely to manifest many of the same symptoms as those with primary attention deficits, but their inattention is secondary either to an information processing problem (such as a receptive language disability or a disorder of short-term memory) or, alternatively, to significant emotional preoccupations and anxieties. Children with information-processing problems may "tune out" and become inattentive, fidgety, and impulsive as a response to the futility of struggling to decode words or perceive symbols. Children with serious psychosocial problems may be "drained" of attentional strength because their thoughts are elsewhere.

Situational inattention is a less pervasive form of attention deficit, which is situation-specific in that it is likely to be the result of mismatchings between external expectations and a child's characteristics. An incorrect school or classroom placement may precipitate inattention, or a child whose home value system and cultural milieu differ significantly from those in the school may become inattentive and disorganized in the classroom.

Finally, one must acknowledge the existence of *mixed forms* of chronic attention deficit. Some children may have primary weaknesses of attention accompanied by learning disorders and anxiety. Some also will have situational inattention, as they are placed in classrooms that may not meet their needs. A basic differentiation, such as this, can be important in educational planning and in the design of studies of natural history as well as for intervention.

From a clinical standpoint, each child needs to be assessed as an individual person rather than as a representative of a syndrome.[57] His or her unique array of traits (Figure) will be the major determinant of therapy, of educational planning, and of the type of counseling and anticipatory guidance. The clinician must be sensitive to the fact that, although these children are likely to share some traits in common, there is marked heterogeneity and major differences among them with regard to service needs.

When one turns to the question of cause, there may be even more variation. It is likely that widely diverse causes exist, ranging from genetic determinants, to perinatal stresses, to acquired CNS insults, early environmental influences, and perhaps combinations of these.[5,39,58]

CONCLUSION

Although they are far from conclusive, studies of adult outcome reinforce the notion that there exists a highly vulnerable subset of our children, that early identification is likely to be crucial, and that we need to direct our clinical and research efforts toward enhancing their quality of life. It would seem, however, injudicious to presume homogeneity among these children. We are in fact *not* dealing with a well-circumscribed syndrome or functional disease entity. Hyperactivity is more than a symptom. It is also more than a symptom complex. The behaviors enumerated represent nonspecific symptoms, the outward indicators that not all is well at the interface between an environment and a possibly disordered CNS.[59] It may be that an attention deficit is to developmental dysfunction as fever is to infection. As a clinical phenomenon, it is unlikely ever to become etiologically and therapeutically specific. It should be conceptualized as a vital subject area for developmental pediatrics (and other disciplines) rather than a clearly definable syndrome. It is likely that "hyperactivity" is both a complex symptom and a complex symptom complex. We prefer not to use the term!

Radiological Case of the Month

Lionel W. Young, MD; Contributed by I. Gershman, MD, Peter R. Simon, MD, MPH

A 17-year-old girl was evaluated at the Roger Williams General Hospital, Providence, RI, because of multiple injuries received during an assault. Roentgenograms of her pelvis and long bones showed no evidence of fractures or dislocations (Fig 1). However, an unusual pattern was noted in the bones.

She previously had been well, without complaints of limb or bone pain, joint swelling or stiffness. Her parents, both 40 years old, were unrelated by birth and came from mixed ethnic backgrounds. Pelvic roentgenograms of her father (Fig 2) and her 13-year-old brother (Fig 3) showed similar skeletal patterns, but her sister and mother were unaffected.

Osteopoikilosis: Familial Documentation

Osteopoikilosis (spotted bones) is a rare, clinically harmless condition classified in the orthopedic and pathology literature[1] as an anomaly of bone. It has been reported about 150 times in series published in both the radiologic and orthopedic literature.[1,2]

The condition, although first reported in 1905 by Stieda,[3] was fully described clinically in 1914 by Albers-Schonberg[4] and Ledoux-Lebard et al,[5] and histopathologically by Schmorl[6] in 1931. Usually, the diagnosis of osteopoikilosis is a chance discovery on a roentgenographic examination for other reasons. Affected individuals show small foci of compact osseous tissue interspersed through the spongy bone. The spotted or mottled appearance on roentgenogram is produced by these discrete or clustered, round or slightly oval radiopacities.

This entity is uncommon. Jonasch,[7] in a series of 211,000 unselected roentgenograms, identified only 12 cases (six cases per 100,000). Reports tend to suggest that it occurs most often between the ages of 15 and 60 years of age although cases in newborns and even a 4-month-old fetus[8] have been discovered. No sex seems to be preponderant.

The etiology of the condition is unknown. However, autosomal dominant mendelian inheritance with variable expressivity has been established. In one family, the condition has been shown in four generations.[2]

A multitude of conditions have been reported as associated with osteopoikilosis.[9] Dermatofibrosis lenticularis disseminata and subcutaneous fibrous nodules are the two most commonly mentioned. Whether these and other conditions show an increased incidence in the presence of osteopoikilosis has not been documented. Osteopoikilosis is a benign condition, with little or no clinical importance, and should not be confused with more serious disorders of bone.[10]

Clinical Memoranda

Pseudodiverticulum of the Esophagus in the Newborn Infant

Atresia of the esophagus, with or without tracheoesophageal fistula, is the most common congenital malformation of the upper gastrointestinal (GI) tract. Duplication of the esophagus and diverticulum (outpouching of all layers of the esophagus) are among the rare but still important congenital esophageal lesions. Lack of continuity of the esophageal wall could be congenital, disease related, or the end result of a diagnostic or therapeutic maneuver.

See p 367.

A pseudodiverticulum is a traumatic perforation of the esophagus that affects only the mucosa and submucosa but spares the muscularis.[1] The lack of familiarity with its clinical and radiologic signs may result in unnecessary diagnostic delays or therapeutic misadventures. Fourteen cases of esophageal pseudodiverticulum have previously been reported in the literature. To our knowledge, this report is of the smallest premature infant affected with this condition, who was treated conservatively and experienced prolonged spontaneous closure.

Report of a Case.—A female infant was born at 28 weeks of gestation to a 17-year-old girl. Apgar scores were 3 at one minute and 8 at five minutes. Oropharyngeal suctioning with a polyvinyl de Lee catheter and endotracheal intubation were necessary before the resuscitation was completed. The birth weight was 960 g, appropriate for age at about 28 weeks' gestation.

One hour after admission, the patient had respiratory failure requiring endotracheal intubation and artificial ventilation on a pressure-controlled respirator. At 4 hours of age, large amounts of mucous material were suctioned with a de Lee catheter from the oropharynx. One hour later, several attempts to place an orogastric tube failed. A chest and abdominal film showed the position of the orogastric tube to be at the upper third of the esophagus, the absence of abdominal air, and a reticulogranular appearance. The infant was then placed on a regimen of nothing per mouth (NPO), and further diagnostic studies were delayed until the hyaline membrane disease (HMD) improved. The course of HMD peaked at 48 hours of life, with a right pneumothorax that was corrected by a polyvinyl hydrochloride thoracotomy tube insertion and continuous suction.

At 6 days of life, the patient was extubated, but owing to the recurrence of severe apneic spells, she had to be reintubated four hours later. Two days later, an orogastric tube was passed into the stomach without difficulty. This maneuver ruled out the possibility of a blind proximal esophageal pouch. Gavage feedings were started and promptly discontinued after they were found to be associated with cyanosis and respiratory distress. To rule out an H-type fistula, an intragastric oxygen test was performed,[2] which was negative. An esophagram was performed under fluoroscopy, identifying a pseudodiverticulum arising from the posterior pharyngeal wall at the C-5 level and extending inferiorly to the T-2 level. The same day, the infant was successfully extubated and the subsequent course was complicated only by one episode of atelectasis of the right lung, which was corrected by deep suctioning of the bronchial tree.

The patient received total parenteral nutrition for the first 18 days of life and was then given polytube feedings of lactose-free, medium triglycerides formula (Portagen). The indwelling orogastric catheters were replaced every third day without difficulties, and intermittent gavage feedings were restarted at 30 days of life and were continued for another month before nipple feedings.

The hospital course was transiently complicated by hyperbilirubinemia, ketonuria, and edema. At 67 days of age, an esophagram still indicated the presence of a pseudodiverticulum. One week later, the infant was discharged while feeding by nipple without difficulties.

Two weeks after discharge, she was admitted to Columbus (Ohio) Children's Hospital for evaluation of apneic spells. These episodes were considered to be seizure equivalents, and the patient was discharged on a regimen of elixir of phenobarbital sodium (5 mg/kg/day).

At 4 months of age, she had a viral laryngotracheobronchitis severe enough to require hospitalization. During this admission, a follow-up esophagram was performed, and complete disappearance of the pseudodiverticulum was documented. When examined at 8 months of age, the infant seemed to be growing and developing normally and to be able to eat solid food without difficulty.

Comment.—One of every two very small premature infants ($\leq$ 1,000 g) requires endotracheal intubation in the delivery room.[3] Oropharyngeal suctioning,[4-7] endotracheal intubation,[7,8] and nasogastric tube passage[9] have all been associated with pseudodiverticulum formation; and all these procedures were performed on our patient prior to the initial clinical signs. The most characteristic sign of a pseudodiverticulum is the failure to pass a nasogastric tube in the absence of esophageal atresia. This is thought to be due more to cricopharyngeal spasm than to penetration into the newly formed tract. Passage of an orogastric tube without difficulty, even when the lesion was still open, reinforces the concept that cricopharyngeal spasm may have been the main reason for the obstruction early in the course. Increased salivation, cyanosis, and dyspnea during feedings have also been associated with these rare lesions of the esophagus.[4-9]

Clinical Signs	No. of Cases
Increased salivation mucus drooling	9/15
Cyanosis and/or respiratory distress syndrome	9/15
Feeding difficulties, vomiting, choking	8/15
Inability to pass orogastric or nasogastric tube	7/15

At the time when an H-type esophageal fistula was considered, an intragastric oxygen test[2] was performed. This new technique is promising, but its accuracy should be evaluated with a larger patient series.

An esophagram is the diagnostic procedure of choice for visualization of the pseudodiverticulum. Roentgenographic signs of pseudodiverticulum have been observed by Ducharme et al and are based on location, configuration, and size of the lesion.[4] Adjunctive procedures are laryngoscopy and esophagoscopy.[4-7]

If one would wait until the cricopharyngeal spasm is over, it might be possible to pass an orogastric tube, ruling out esophageal atresia. In our case, orogastric passage was successfully done at the eighth day of life.

Although 14 cases of pseudodiverticulum have been reported to date,[1,4-6,8,9] this condition remains extremely rare. Ekloff et al[6] briefly mentioned six unreported cases, and we know of at least another one in our community. Considering the frequency of aggressive instrumentation of the upper airway and GI tract, we suspect this entity may occur more often than hitherto reported. Of the reported cases, information about gestational age was available in only nine instances. Four of these nine newborns were known to be premature. Seven patients underwent exploratory thoracotomy and resection, and ligation of the pseudodiverticulum was performed on four of them.

Ekloff et al[6] summarized their expe-

rience with three cases by strongly advocating a nonsurgical approach, close supervision, and polytube feedings. Astley and Roberts,[9] Ducharme et al,[4] and Edison and Holinger[5] endorsed the conservative approach of Ekloff et al. In the report by Girdany et al,[1] two patients were operated on and one died; and in the report by Armstrong et al,[8] the only patient on whom surgery was performed survived.

Since nonsurgical treatment has been successful in eight cases and spontaneous closure has been reported in 11 out of the 15 cases, it is our opinion that the treatment of pseudodiverticulum of the esophagus should be a conservative one. Spontaneous closure has been reported to occur between 3 to 124 days of life. In nine of 11 cases, this was documented before the 16th day of life, and it is likely that it may have occurred earlier. It would seem advisable to keep the patient on a regimen of NPO for at least two weeks while being supported by partial or total parenteral nutrition via a peripheral vein.[10] At that time, another esophagram should be performed, and if the pseudodiverticulum is by then closed, nipple feeding in the full-term infant and gavage feeding in the premature infant should be started. We do not advocate the use of gastrostomy as a feeding technique in this condition since it has been associated with increased mortality in the premature infant.[11] Furthermore, the natural history of this condition, the possibility of spontaneous early closure of the pseudodiverticulum, and the availability of total or partial parenteral nutrition support the conservative approach.

Successful Treatment of Rupture of Normal Spleen in Newborn

Diagnosis and successful repair of the ruptured spleen or liver in the newborn is rare. More autopsy diagnoses are reported[1-3] of this complication of delivery than diagnoses of surviving cases.[3-5] A case is reported where the diagnosis of a ruptured normal spleen was established and splenectomy was performed within the first 24 hours of life. The usefulness of the available diagnostic clinical and roentgenographic signs is discussed.

Report of a Case.—A 3.975-kg male infant was born after an uncomplicated 40-week gestation to a 17-year-old woman. Pertinent status of the mother was as follows: gravida 3, para 2, negative VDRL, and a blood type of group B, Rh positive. Labor was 2½ hours' duration. A pudendal block was used. Rupture of the membranes occurred 30 minutes before delivery; the baby was a vertex presentation. The one-minute Apgar score was 9. Maternal blood loss was estimated to be 300 mL. Cord blood hemoglobin level was 13.5 g/dL and the hematocrit level was 41.5%. The baby had group B, Rh positive blood with negative Coombs' test. Physical examination within 12 hours after birth showed a normal male newborn without signs of traumatic delivery. Routine nursery care was begun.

At 20 hours of age, after returning from feeding by the mother, the neonate became pale and tachypneic, and abdominal distention developed. Systolic blood pressure was undetectable. Rectal examination and return from nasogastric tube showed no blood in the rectum or stomach, respectively. He received a transfusion of 30 mL of blood after a blood sample was obtained. Laboratory studies disclosed the following values: hemoglobin, 6.4 g/dL; hematocrit, 17.2%; and WBCs, platelets, reticulocytes, total bilirubin, and hemostasis were normal. An abdominal roentgenogram failed to visualize the stomach; no masses or calcifications were noted. Roentgenographic examination of the stomach showed anterior and medial displacement without extravasation of the opaque material. Paracentesis showed blood in the abdomen that did not clot. Posttransfusion hemoglobin and hematocrit levels were 7.1 mg/dL and 21.5%, respectively. The baby was given another transfusion of 50 mL of fresh whole blood.

At surgery, approximately 150 mL of blood and clots were found in the abdominal cavity. A large retroperitoneal nonpulsatile hematoma was found over the left kidney and extended inferiorly to the level of the aortic bifurcation. The posterior surface of the spleen showed a capsular tear at the splenorenal ligament. There were no thoracic or diaphragmatic contusions and no intra-abdominal or retroperitoneal abnormalities.

A splenectomy was performed. Salvage of spleen was not performed due to the gravity of patient's condition. The postoperative course was uneventful.

The spleen weighed 7 g and measured 4.5 × 3.0 × 1.5 cm. The capsular surface was normal with the exception of the capsular and parenchymal tear at the posterior hilar area. Results of the histopathologic examination were normal.

Comment.—The pathogenesis of the rupture of the spleen during or after an uneventful delivery is an enigma.[6] Gruenwald[1] believed that an important mechanism is an increased intrathoracic pressure that forces the liver and spleen out of the diaphragmatic hollow, causing severe tension in their supporting ligaments.

Our patient was a full-term male without primary disease and the delivery was neither precipitous nor difficult. The spleen was normal in size and structure. A splenic tear at the site of implantation of splenorenal ligament was found. Therefore, it seems that an unusual pressure on our patient's thorax might have caused rupture of a normal spleen.

Splenic rupture is a surgical emergency and the diagnosis becomes more difficult when one deals with nontraumatic delivery and an otherwise normal newborn. One must keep in mind the following two important observations: first, normal labor and delivery do not exclude the diagnosis of intra-abdominal trauma and second, splenic rupture occurs in two

stages—formation of a subcapsular hematoma, followed by urgent symptoms that occur only when the capsule eventually gives way. This is why the classical triad of unexplained blood loss, abdominal distention, and roentgenographic evidence of intraperitoneal fluid[4] is not always present.[5]

Several roentgenographic findings are consistent with splenic trauma: total body opacification,[7] free abdominal fluid, and "floating" gas-filled loops in a plain film, displacement of the stomach.[8] However, no single group of roentgenographic findings is consistently associated with splenic trauma.[9]

In our patient, the diagnosis of splenic rupture was established and operation was performed within the first 24 hours of life after an abdominal paracentesis showed hemoperitoneum. Although abdominal paracentesis led to more prompt diagnosis and operative intervention during the second stage of splenic rupture, we believe that all of the available diagnostic tools, including splenic scintiscan,[10] should be used to establish the diagnosis at an earlier stage when splenic salvage[11,12] may be performed. The latter is important, particularly in the very young infant to avoid overwhelming infection after splenectomy.[13]

Neonatal Death Associated With Acute Transplacental Ethanol Intoxication

Alcohol is known to produce fetal teratogenicity,[1] neonatal withdrawal,[2] and acute transplacental intoxication.[3] We report a case of death in a neonate attributed to transplacental alcohol, used in an attempt to prevent premature parturition.

Report of a Case.—The mother, a 20-year-old primigravida in her 32nd week of an uncomplicated pregnancy, was prescribed strict bed rest and oral vodka, 30 mL thrice daily, to retard early onset of labor. Two days later, with continued contractions, the amount was increased and consumed in the volume of 30 mL/hr. Twelve hours thereafter, she was hospitalized with regular contractions and a slightly bloody vaginal discharge.

A single intravenous (IV) dose of 10 mg of morphine sulfate and a continuous IV drip of 10% ethanol were administered. During the next four hours, she became progressively intoxicated, unresponsive, areflexic, and unconscious, necessitating discontinuation of the ethanol drip; a total of 160 g of ethanol had been administered.

Two hours later, an amniotomy was performed followed by immediate vertex delivery of a severely depressed 1,420-g female infant. Apgar scores were 2 at one minute and 3 at five minutes. Normal fetal heart rates by auscultation were recorded up to half an hour before delivery; none were monitored thereafter. Resuscitation required endotracheal intubation, bag-to-tube ventilation with 100% oxygen, and IV infusions of sodium bicarbonate and epinephrine hydrochloride. Despite these efforts, the infant remained cyanotic, flaccid, unresponsive, and intermittently bradycardiac, and she had no spontaneous respiratory effort. Her temperature decreased to 34 °C. Umbilical venous blood gases at half an hour of life showed a Po_2 of 26 mm Hg, a Pco_2 of 74 mm Hg, and a pH of 7.05. Vigorous supportive measures were continued.

The infant was transported from the community hospital to the newborn intensive care center at the University of Utah, Salt Lake City, arriving at 5 hours of life. On our initial examination, in addition to the persistence of the previously described morbid findings, we found fixed dilated pupils, hypotension, and poor peripheral perfusion. The umbilical arterial blood pressure was 28 mm Hg. Hypothermia had been corrected. Laboratory studies revealed a nearly pure metabolic acidosis, a pH of 7.15, a Pco_2 of 43 mm Hg, and a base deficit of 15 mEq/L. This degree of metabolic acidosis persisted, despite base therapy and blood volume correction. The central hematocrit was 58%. Oxygenation remained marginal at best despite 100% inspired oxygen and artificial ventilation. A chest roentgenogram showed diffuse patchy infiltrates. Blood and CSF cultures indicated no growth of organisms.

The infant died at 56 hours of age, having shown persistent hypoxia, metabolic acidosis, and progressive bradycardia. Permission for an autopsy was denied. The mother resumed full consciousness during a 24-hour period after delivery.

Comment.—The Table lists serial blood alcohol levels as obtained for this mother and her infant. Therapeutic levels for prevention of premature parturition range from 90 to 160 mg/dL, intoxication at 200 to 300 mg/dL, coma at 350 to 500 mg/dL, and deaths have occurred at 450 to 500 mg/dL. Toxic levels have not been published for neonates. This mother's course correlated well with her alcohol intake and recorded blood levels.

Ethanol crosses the placental barrier freely; cord blood levels are about 20% lower than simultaneous maternal levels.[4] Elimination of alcohol is delayed in neonates, at a rate only about half as fast as their mothers[5]; in our patient, the rate of decrease in blood alcohol concentration was 15 mg/dL/hr while the mother's rate was 27 mg/dL/hr. Alcohol dehydrogenase activity is known to be low in human fetal liver, reaching only 20% of adult activity by term, a reasonable explanation for delayed metabolism of alcohol in newborns.[6] One might have expected that, as our infant's serum level decreased, there would have been noticeable clinical improvement, which was not observed. We suggest severe and prolonged ethanol toxic effects produced irreversible damage either directly from alcohol or indirectly through induced severe metabolic acidosis, with subsequent hypoxia and shock in this neonate. Transplacental ethanol has been shown to produce severe metabolic acidosis in fetal sheep.[7] We speculate that alcohol was

Blood Ethanol Levels for Infant and Mother

responsible for this infant's moribund state. We cannot know to what extent prematurity, a history of vaginal bleeding of unresolved etiology, or maternal morphine infusion added to the effects of alcohol or contributed independently to this infant's death. Further case reporting and animal experimentation is needed to delineate the toxicity of alcohol for the fetus and neonate.

Acute neonatal ethanol intoxication has been reported when mothers consumed excessive amounts of alcohol[3] and when premature infants received IV fluids containing alcohol[8]; to our knowledge, neonatal death from alcohol has not been reported previously. This case has important implications for both the obstetrician and the pediatrician.

Published support for the oral use of alcohol in delaying parturition is limited.[9] Controversy even exists concerning the efficacy of intravenously administered alcohol.[10,11] As the present case illustrates, orally administered alcohol may act cumulatively with IV alcohol. Both a threatened premature labor and the use of alcohol to prevent it represent complex situations; hence, it seems appropriate to suggest that such patients should be managed in the hospital.

Treatment of severe fetal-neonatal ethanol intoxication should include prompt and vigorous resuscitation, with special attention to correction of metabolic acidosis. Care should be provided in a newborn intensive care unit. As far as we know, there have been no reported experiences of two additional logical modes of treatment of a severe neonatal ethanol toxic condition, namely, peritoneal dialysis and/or exchange transfusion. In view of ethanol's small molecular weight, high solubility, and primary distribution in the fluid phase of the body, peritoneal dialysis[12] or exchange transfusion may have a place in the treatment. Peritoneal dialysis has been used with success to reduce serum ethanol levels in an older child.[13] Both deserve more consideration.

Intracranial Dermoid Cyst: Diagnosis by Computerized Tomography

Dermoid and epidermoid cysts are closely related benign, cystic tumors that occur throughout the CNS. Their slow growth may result in a long history of obscure symptoms, and they may attain large size with permanent neurologic impairment before the correct diagnosis is established. The angiographic appearance does not differ from other avascular masses. Computerized tomography (CT) can suggest a correct diagnosis.

Gawler et al[1] first described low absorption values in an intracranial, fat-containing dermoid cyst, as well as low absorption values in fat-containing craniopharyngiomas and teratomas. Other authors have reported both low and high absorption values in epidermoid cysts, apparently related to the nature of the contents.[2]

Report of a Case.—A 12-year-old girl's symptoms began approximately three years prior to this admission. At that time, she was noted to have a mild exophthalmus with no clinical evidence of hyperthyroidism; thyroid function studies showed no abnormalities. She was subsequently noted to have a rotational nystagmus, and conventional skull roentgenograms demonstrated a large calcific density in the region of the posterior fossa. The patient was seen by a neurosurgeon. Surgery was not advised because of the patient's satisfactory clinical course.

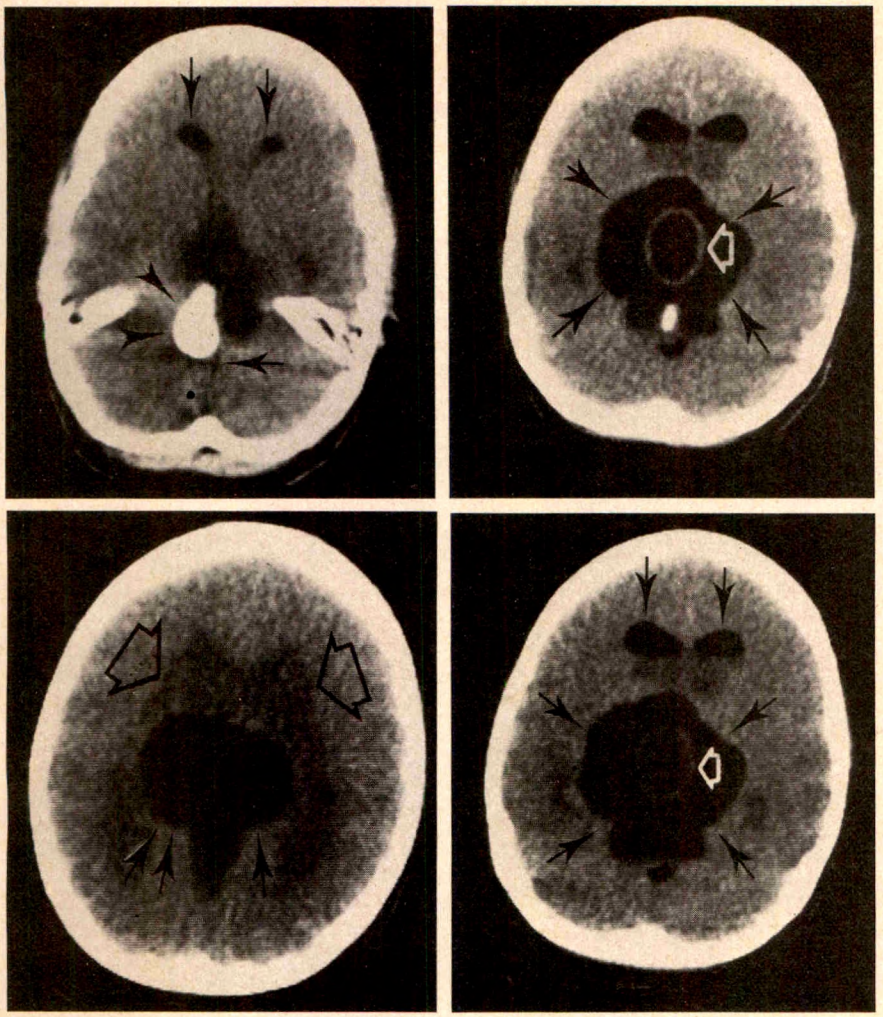
At age 12 years, the patient suddenly had severe bifrontal headaches, mild meningeal signs, and bilateral papilledema.

Cranial CT (Figure) showed a large, well-circumscribed cystic tumor of fat density. The tumor seemed to arise in the posterior fossa and to extend through the incisura dorsally, to the left of the falx cerebri, and inferiorly, to the lower margin of the fourth ventricle. There was severe ventricular dilation consistent with obstructive hydrocephalus. Free fat was noted in the lateral and third ventricles. The tumor contained a large calcific density. The free fat in the ventricles (low absorptive values) was indicative of intraventricular cyst rupture, a not uncommon complication of this lesion.

The patient underwent decompressive surgery, and a shunt procedure was performed, with notable clinical improvement. Definitive surgery was attempted three weeks later, but because of the large size, the tumor was not completely accessible and, therefore, was only partially excised. The patient had a difficult postoperative course, and on the sixth postoperative day, she became comatose and died. The operating surgeon believed that the tumor arose in the region of the pineal gland.

Histological studies indicated a cystic structure with a lining of stratified squamous epithelium. The cyst contained large quantities of keratin and hair. Dermal appendages, fat, and abnormally thick vessels were encountered in the walls of the cyst, along with foci of gliotic white matter. The opinion of the pathologist was that this represented a dermoid cyst arising posteriorly to the third ventricle.

Comment.—Pathologically, dermoid and epidermoid cysts of the CNS are cystic structures of variable size, sur-



Representative plain (top left and right and bottom left) and postcontrast injection (bottom right) scans. Top left, A "tooth"-shaped density (arrow heads) is present just above fourth ventricle (horizontal arrow) at level of pineal cistern. Fat (low absorptive values) fluid levels are present in frontal horns (vertical arrows). Top right, Image is at level of third ventricle and frontal horns. Fat-containing mass (diagonal arrows) has extended superiorly through tentorial incisura to collapse third ventricle, which is not visualized. Central loculation (open arrow), within cystic mass, is present. Fat fluid levels (vertical arrows) are present in frontal horns. Bottom left, Image is at level of lateral ventricles (open arrows), which are massively dilated due to obstruction at foramen of Monro. Mass (solid arrows) has extended between two lateral ventricles. Bottom right, Postintravenous contrast infusion computerized tomographic image at same level as image at top right. Periphery of mass (solid arrows) and central loculation (open arrow) is better visualized (enhanced) by contrast infusion.

rounded by a capsule of dense, fibrous connective tissue and lined by stratified squamous epithelium. Epidermoid cysts are lined solely by squamous epithelium. The lining of a dermoid cyst may also include skin appendages such as hair follicles, sweat, and sebaceous glands. Cyst contents may differ, with the dermoid cyst containing hair and large quantities of fat and with the epidermoid cyst containing only keratin, cellular debris, and cholesterol crystals.

The origin of these lesions is obscure. Most authors suspect a developmental process resulting from the inclusion of a segment of cutaneous ectoderm with neural ectoderm at the time the neural groove closes and separates, about the fourth week of gestation.[3] Trauma has been implicated in some of these tumors. A third possibility is that these lesions represent benign cystic teratomas that differentiate and develop from primitive totipotential embryonic rests, similar to dermoid cysts of the ovary.

The incidence of these lesions in the CNS has been estimated to 0.4% of all tumors, the epidermoid variety being more common than the dermoid. Epidermoids are also known as "pearly" tumors or cholesteotomas although they are not related to the cholesteotomas found in the middle ear in chronic mastoiditis. Dermoid cysts generally occur prior to age 20 years. Epidermoids tend to occur in older patients, with the peak incidence at about age 35 years.

These lesions tend to occur in the midline, usually in the juxtasellar or pineal regions or between the cerebellar hemispheres. Epidermoid cysts have been reported in the cerebellopontine angles and the ventricular system, especially the fourth ventricle.

Computerized tomography can be helpful as the fat within the cyst produces low absorptive values. Occasionally, epidermoid cysts will have high absorptive values, thought to be secondary to the high keratin content. When this is the case, the cysts cannot be differentiated from other solid tumor mass. Computerized tomography will demonstrate, as do conventional roentgenograms, the presence of teeth, bone, etc, as well as locating their position within the cyst.

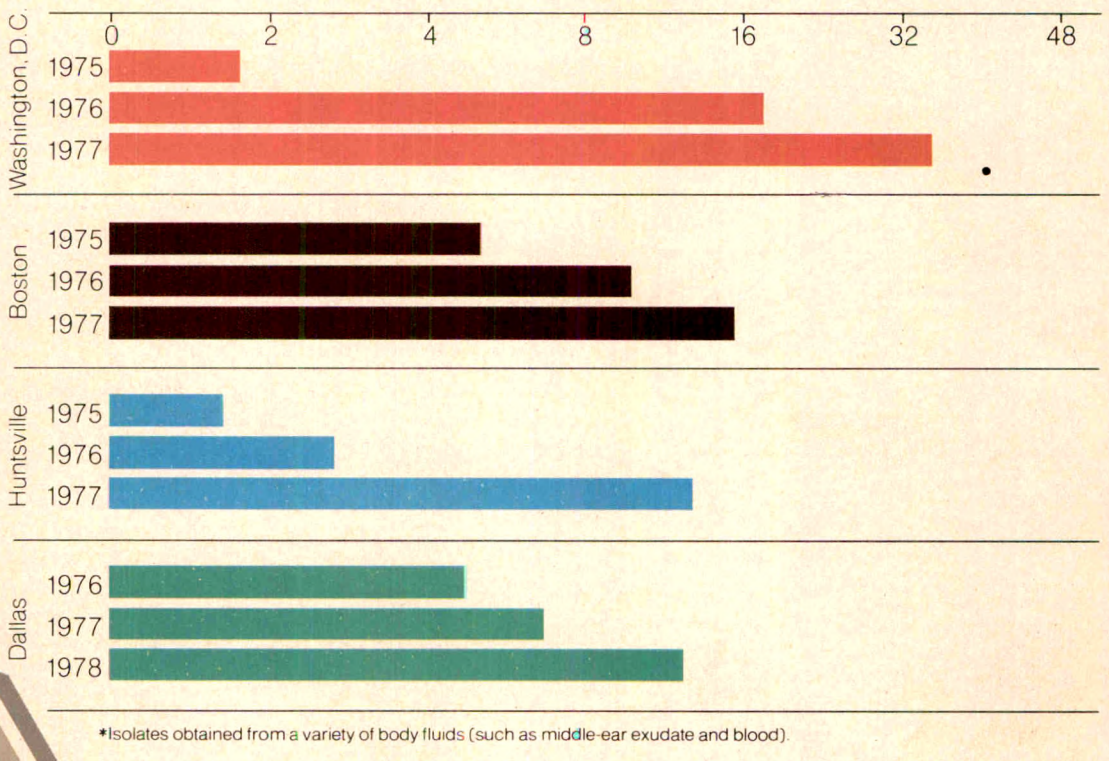
Increasing resistance o



Brief Summary.
Consult the package literature for prescribing information.

Indications and Usage: Ceclor®(cefaclor, Lilly) is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms:

Otitis media caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae,* staphylococci, and *S. pyogenes* (group A beta-hemolytic streptococci).

Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor.

Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY. THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PE CILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS TO BOTH DRUG CLASSES (INCL ING ANAPHYLAXIS AFTER PARENTERAL USE)

Antibiotics, including Ceclor® (cefaclor, Lilly), should administered cautiously to any patient who has demonstrated some form of allergy, particularly to drugs.

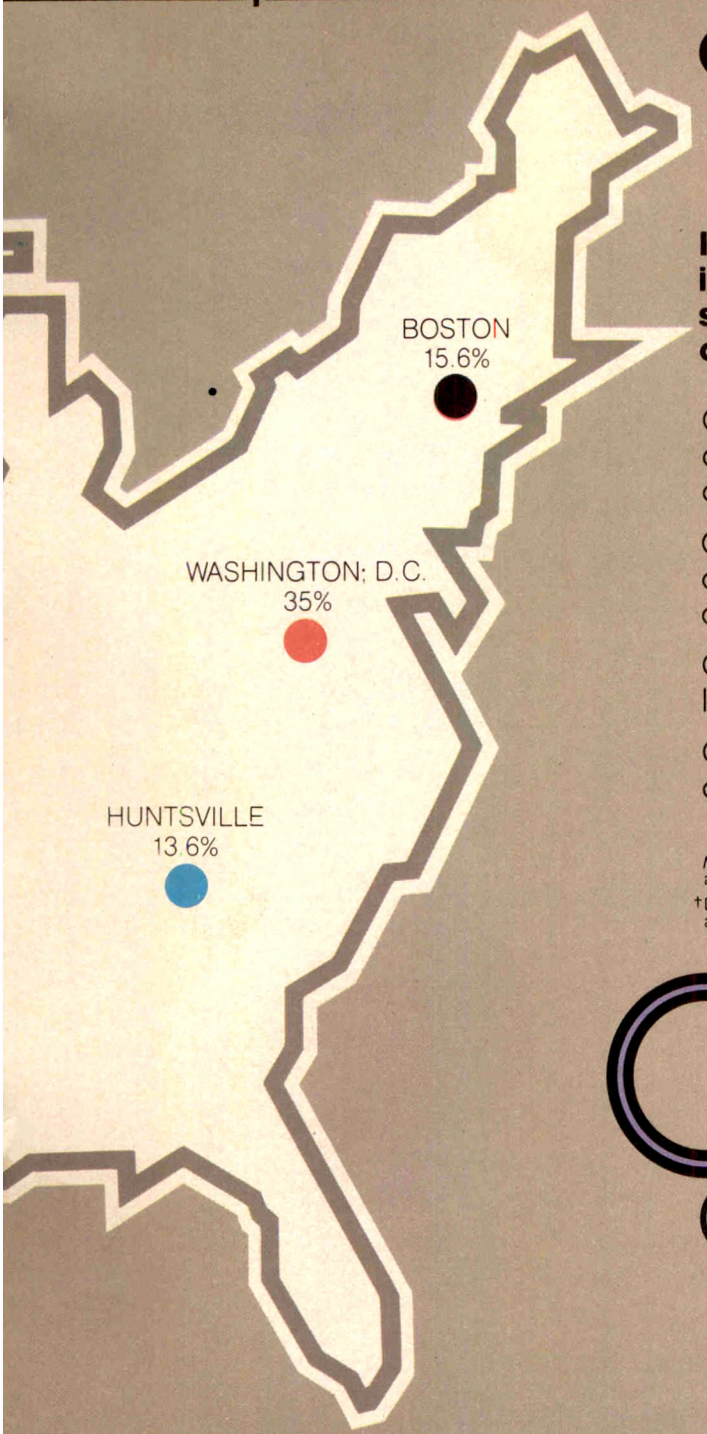
Precautions: If an allergic reaction to cefaclor occurs, th drug should be discontinued, and, if necessary, the pat should be treated with appropriate agents, e.g., presso amines, antihistamines, or corticosteroids.

Prolonged use of cefaclor may result in the overgrow of nonsusceptible organisms. Careful observation of th patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Positive direct Coombs tests have been reported duri treatment with the cephalosporin antibiotics. In hemato logic studies or in transfusion cross-matching procedu when antiglobulin tests are performed on the minor side in Coombs testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it

Haemophilus influenzae in otitis media...

a valid concern



In many areas of the country, increasing numbers of *H. influenzae* show resistance to conventional antibiotic therapy.[1-3]

Ceclor is effective in the treatment of otitis media†, including that due to some ampicillin-resistant strains of *H. influenzae*.[4-9]

Ceclor has been shown to be clinically and bacteriologically effective in treating otitis media due to susceptible organisms.[10]

Ceclor is available in two pleasant-tasting liquids.

Ceclor provides effective single-agent antibiotic therapy for otitis media.

Note: Ceclor is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

†Due to susceptible strains of *Streptococcus pneumoniae*, *H. influenzae*, staphylococci, and *S. pyogenes*.

125-mg/5-ml and 250-mg/5-ml oral suspensions

Ceclor®

cefaclor

should be recognized that a positive Coombs test may be due to the drug.

Ceclor ® (cefaclor, Lilly) should be administered with caution in the presence of markedly impaired renal function. Under such a condition, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended.

Usage in Pregnancy—Although no teratogenic or antifertility effects were seen in reproduction studies in mice and rats receiving up to 12 times the maximum human dose or in ferrets given three times the maximum human dose, the safety of this drug for use in human pregnancy has not been established. The benefits of the drug in pregnant women should be weighed against a possible risk to the fetus.

Usage in Infancy—Safety of this product for use in infants less than one month of age has not been established.

Adverse Reactions: In clinical studies in 1493 patients, adverse effects considered related to cefaclor therapy were uncommon and are listed below:

Gastrointestinal symptoms occurred in about 2.5 percent of patients and included diarrhea (1 in 70) and nausea and vomiting (1 in 90).

Hypersensitivity reactions were reported in about 1.5 percent of patients and included morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs tests each occurred in less than 1 in 200 patients.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain—Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic—Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic—Transient fluctuations in leukocyte count, predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal—Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

You can help the ADD* child with Cylert
(pemoline)

Day-long behavior therapy without dosing problems at school

Impressive all-day control.

Cylert works extremely well, given an adequate period of trial. Single daily doses are as effective for behavior control as multiple doses of methylphenidate or amphetamines. Blood levels are well sustained, without necessity for multidose administration.

No troublesome midday dose.

Cylert avoids problems of taking a drug at school. No involvement of school personnel. No peer teasing about noon-time dosing. The parents manage all medication, and the child carries no drugs. (And note that Cylert is Schedule IV, not II.)

Cylert® (pemoline) C IV

18.75, 37.5, 75 mg tablets; 37.5 mg chewables

Just once a day. At home.

*ADD: Attention Deficit Disorder (formerly called MBD, Minimal Brain Dysfunction), or the Hyperkinetic Syndrome. Please see next page for Brief Summary.

ABBOTT

9083319

Cylert® (pemoline)

DESCRIPTION: CYLERT (pemoline) is a central nervous system stimulant. Pemoline is structurally dissimilar to the amphetamines and methylphenidate.

It is an oxazolidine compound and is chemically identified as 2-amino-5-phenyl-2-oxazolin-4-one.

Pemoline is a white, tasteless, odorless powder, relatively insoluble (less than 1 mg./ml.) in water, chloroform, ether, acetone, and benzene; its solubility in 95% ethyl alcohol is 2.2 mg./ml.

CYLERT (pemoline) is supplied as tablets for oral administration.

CLINICAL PHARMACOLOGY: CYLERT (pemoline) has a pharmacological activity similar to that of other known central nervous system stimulants; however, it has minimal sympathomimetic effects. Although studies indicate that pemoline may act in animals through dopaminergic mechanisms, the exact mechanism and site of action of the drug in man is not known.

There is neither specific evidence which clearly establishes the mechanism whereby CYLERT produces its mental and behavioral effects in children, nor conclusive evidence regarding how these effects relate to the condition of the central nervous system.

The serum half-life of pemoline is approximately 12 hours. Peak serum levels of the drug occur within 2 to 4 hours after ingestion of a single dose. Multiple dose studies in adults at several dose levels indicate that steady state is reached in approximately 2 to 3 days.

Metabolites of pemoline include pemoline conjugate, pemoline dione, mandelic acid, and unidentified polar compounds. CYLERT is excreted primarily by the kidneys; approximately 75% of an oral dose is recovered in the urine within 24 hours. Approximately 43% of pemoline is excreted unchanged.

CYLERT (pemoline) has a gradual onset of action. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

INDICATIONS: CYLERT is indicated as an integral part of a total treatment program which typically includes other remedial measures (psychological, educational, social) for a stabilizing effect in children with a behavioral syndrome characterized by the following group of developmentally inappropriate symptoms: moderate to severe distractibility, short attention span, hyperactivity, emotional lability, and impulsivity. The diagnosis of this syndrome should not be made with finality when these symptoms are only of comparatively recent origin. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present, and a diagnosis of central nervous system dysfunction may or may not be warranted.

Attention Deficit Disorder and Hyperkinetic Syndrome are among the terms being used to describe the above signs and symptoms. In the past, a variety of terms has been associated with these signs and symptoms, including: Minimal Brain Dysfunction, Hyperkinetic Reaction of Childhood, Hyperkinetic Syndrome, Hyperactive Child Syndrome, Minimal Brain Damage, Minimal Cerebral Dysfunction, and Minor Cerebral Dysfunction.

CONTRAINDICATIONS: CYLERT (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

WARNINGS: CYLERT is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Clinical experience suggests that in psychotic children, administration of CYLERT may exacerbate symptoms of behavior disturbance and thought disorder.

Data are inadequate to determine whether chronic administration of CYLERT may be associated with growth inhibition; therefore, growth should be monitored during treatment.

PRECAUTIONS: Drug treatment is not indicated in all cases of the behavioral syndrome characterized by moderate to severe distractibility, short attention span, hyperactivity, emotional lability and impulsivity. It should be considered only in light of the complete history and evaluation of the child. The decision to prescribe CYLERT should depend on the physician's assessment of the chronicity and severity of the child's symptoms and their appropriateness for his/her age. Prescription should not depend solely on the presence of one or more of the behavioral characteristics.

When these symptoms are associated with acute stress reactions, treatment with CYLERT is usually not indicated.

Long-term effects of CYLERT in children have not been well established.

Liver function tests should be performed prior to and periodically during therapy with CYLERT. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

CYLERT should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of CYLERT with other drugs has not been studied in humans. Patients who are receiving CYLERT concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

CYLERT failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with CYLERT. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. CYLERT should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of CYLERT (pemoline) for use during pregnancy and lactation has not been established.

Studies in rats have shown an increased incidence of stillbirths and cannibalization when pemoline was administered at a dose of 37.5 mg./kg./day. Postnatal survival of offspring was reduced at doses of 18.75 and 37.5 mg./kg./day.

ADVERSE REACTIONS: Insomnia is the most frequently reported side effect of CYLERT; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking CYLERT, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking CYLERT, a causal relationship between the drug and this clinical finding has not been established.

The following CNS effects have been reported with the use of CYLERT: dyskinetic movements of the tongue, lips, face and extremities, nystagmus and nystagmoid eye movements, and convulsive seizures. A definite causal relationship between CYLERT and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with CYLERT often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

OVERDOSAGE: Signs and symptoms of acute CYLERT overdosage may include agitation, restlessness, hallucinations, dyskinetic movements and tachycardia. The treatment for an acute overdosage of pemoline is essentially the same as that for an overdosage of any CNS stimulant. Management is primarily symptomatic and may include induction of emesis or gastric lavage, sedation, and other appropriate supportive measures.

Results of studies in dogs indicate that extracorporeal hemodialysis may be useful in the management of CYLERT overdosage; forced diuresis and peritoneal dialysis appear to be of little value.

DOSAGE AND ADMINISTRATION: CYLERT (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg./day. This daily dose should be gradually increased by 18.75 mg. at one week intervals until the desired clinical response is obtained. The effective daily dose for most patients will range from 56.25 to 75 mg. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with CYLERT is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration.

Where possible, drug administration should be interrupted occasionally to determine if there is a recurrence of behavioral symptoms sufficient to require continued therapy.

Letters to the Editor

Nutritional Osteomalacia

Sir.—We have read the article by Dwyer et al (JOURNAL 133:134-140, 1979) and have recently observed an adult case of nutritional osteomalacia similar to those presented.

Report of a Case.—A 25-year-old woman came to this hospital with a chief complaint of increasing bone pain in the lower back and hips, which caused difficulty in walking for one year. For the past eight years, she had been on a strictly vegan diet that also excluded fish. Soy products were her only dietary supplement. Her four children (from 11 months to 7 years of age) are also on the same diet. Since the birth of her last child, the patient has continued to lactate and admitted to a 7-kg weight loss in the past year. The patient was referred to the department of rehabilitation medicine due to severe muscle weakness, wasting, and lethargy. She walked with the aid of a cane.

Physical examination showed a 34-kg woman, with a pigeon chest, a left kyphoscoliosis, a positive Chvostek's sign, patellar hyperreflexia, and cephalotruncal disproportion. Dentition was poor and a positive Gowers' sign was noted. Roentgenograms showed the classic pseudofractures (Looser's lines) of the ribs, a widening of the symphysis pubis, mild osteoporosis, diffuse osteopenia, and cupping of the diaphyses of the long bones.

Laboratory findings showed the following levels: total serum calcium, 7.6 mg/dL; magnesium, 1.7 mg/dL; phosphate, 2.6 mg/dL; albumin, 3.9 g/dL; iron, 60.0 μg/dL, with total iron-binding capacity, 426 μg/dL; total serum protein, 6.6 g/dL; serum alkaline phosphatase, 216.4 mU/mL; and serum parathyroid hormone, 406 picogram equivalents (pe)/mL (normal, 163 to 347 pe/mL). Fat was also present in the fecal samples, as well as protein (+2) and ketones (+4) in the urine.

The history, physical examination, laboratory, and roentgenographic findings all point to a diagnosis of vegetarian osteomalacia secondary to inadequate diet, lack of exposure to sunlight, and persistant lactation. The patient discharged herself against medical advice, and hence the children could not be examined.

Comment.—We believe that a vegan diet, as described earlier, with soy substitution is inadequate to prevent metabolic bone disease in adults as well as in children.

Hyperglycemia and Sepsis in a Newborn

Sir.—The article entitled "Recurrent Hyperglycemia Associated With Sepsis in a Newborn" (JOURNAL 133:645-646, 1979) was of interest to me. We have also seen several cases of hyperglycemia associated with sepsis over the past several years. Most of these infants were receiving partial or total intravenous alimentation at the time of the sepsis. Our conclusion was that any infant who did not tolerate a previously tolerated glucose infusion was considered as having sepsis until proven otherwise.

I cannot accept the explanation offered by the authors for the hyperglycemia seen in sepsis: namely, an inadequate insulin response. I would suggest that sepsis, especially that caused by Gram-negative organisms, is associated with endotoxin release. General cellular metabolism is decreased at this time, as is glucose utilization; thus, hyperglycemia would result.

LLOYD I. KRAMER, MD, FAAP

In Reply.—Dr Kramer is correct in pointing out that hyperglycemia in neonates with sepsis may have multiple etiologic factors. We were unable to measure the possible contributing effects of human growth hormone, hydrocortisone, glucagon, or catecholamines. Cryer et al[1] measured these hormones in baboons with *Escherichia coli* sepsis. They concluded that an inadequate insulin response was sufficient to account for hyperglycemia in sepsis.[1] Our patient had serum levels of insulin of 11 μU/mL and 13 μU/mL when her serum concentrations of glucose were 314 mg/dL and 285 mg/dL, respectively. For these glucose levels one would anticipate a greater insulin response.[2] Since our patient was apparently incapable of greater insulin production, I must assume that her response was inadequate. However, I do not have the data to indicate if this inadequate response were the result of sepsis or of the immaturity of a 1.3-kg, 1-month-old, preterm infant.
